Figure 7 Patch types at the Sevilleta National Wildlife Refuge LTER site (SNWR). (a) Location of the SNWR in central New Mexico, US, and location of patch types in the eastern part of the refuge, (b) location of two patch types on the landscape. The transect across the landscape goes through patches dominated by either blue grama, black grama, or the matrix containing both species, (c) cover of blue grama and black grama along the transect, showing one approach for identifying and delineating patches.

species can survive to larger sizes on these early successional mounds. Through time, competition among plants typically reduces the number of species, although plant sizes can be quite large as one or a few plants come to dominate late-successional mounds. This invasion–abandonment cycle results in a shifting mosaic of mound types through time across the landscape (**Figure 8(a)**). Although the species diversity on mounds changes through time, and the location of mound types varies spatially across the landscape, the total numbers of species and patch types remain constant on the scale of the

landscape (**Figure 8(c)**). Therefore, landscape diversity both reflects and determines patterns in diversity at smaller levels of organization, and in particular, species diversity.

Broad-scale drivers such as climate and fire can also affect patterns in diversity within each patch and across the landscape. Black grama is more sensitive to wildfire, livestock grazing, and drought than blue grama (Gosz and Gosz, 1996; Parmenter, 2008). Changes in species production and dominance can result in altered patterns in species diversity, with consequences at the landscape scale (Ryerson and Parmenter,

Figure 8 Small-scale heterogeneity within one black grama patch from [Figure 7b](#). Three types of mounds can be defined based on plant species composition and burrowing activities of bannertail kangaroo rats. (a) Mounds change from one type to another through time as kangaroo rats abandon some mounds and invade others. (b) Number of plant species and average plant size for each mound type. (c) Because the number of mounds within each of the three types is constant in this hypothetical landscape, the total number of species found on the landscape is also constant.

2001). The current frequency of El Niño Southern Oscillation (ENSO) events that increase winter rainfall does not alter the patterns at the landscape scale; however, productivity patterns may respond on an annual basis ([Muldavin et al., 2008](#); [Xia et al., 2010](#)). Climate projections should be considered in modeling how the future ecotone dynamics may change through altered frequency and strength of ENSO events.

Recent experimental manipulations suggest that cover of the dominant grass, black grama, declines drastically (up to 66%) during prolonged drought periods whereas cover of the invasive shrub, creosotebush (*Larrea tridentata*), hardly changes under these same experimental conditions. In addition,

cover of black grama in a lightly grazed pasture along the northern boundary of the SNWR declined 50% relative to long-term ungrazed areas on the Refuge. Thus, the abundance of black grama is negatively affected by common disturbances including grazing, fire, and prolonged drought, all of which may combine to further promote shrub encroachment in this region. However, long-term monitoring of plant cover under undisturbed conditions shows that the abundance of black grama is increasing at a greater rate than Great Plains grasses, such as blue grama. Moreover, experimental nighttime warming year-round favors the growth of black grama ([Collins et al., 2010](#)) but not blue grama. Instead, blue grama

responded more favorably than black grama to low levels of nitrogen addition (Báez *et al.*, 2007). Thus, the composition and abundance of dominant species across this dynamic ecotone are governed by multiple forces that interact in complex ways to affect the rate and direction of landscape change in this aridland ecosystem.

Conclusions

Although much of the current emphasis on biodiversity has been at the level of species, landscape diversity is also important. The preservation and maintenance of multiple levels of organization, including species, populations, communities, and ecosystems, require an understanding of how these various levels interact with their environment across a range of spatial scales. Maintenance of landscape diversity provides a spatial template for the preservation of these smaller levels of organization, and in particular, for species biodiversity. Changes in landscape structure and function through time have important effects on the distribution of resources, with resulting influences on the survival of species in both natural and managed ecosystems. Because of the overwhelming numbers of species, it may be impractical to attempt to conserve species diversity *per se*. By focusing on landscape diversity and the perpetuation of dynamic processes across multiple scales, an attempt can be made to preserve entire ecosystems with their full complement of genetic diversity.

Glossary

Biodiversity A contraction of biological diversity that encompasses all biological variation from the level of genes, through populations, species, and functional groups (and sometimes higher levels such as landscape units).

Ecosystem functioning An umbrella term for the processes operating in an ecosystem.

Ecosystem processes The biogeochemical flows of energy and matter within and between ecosystems, for example, primary production and nutrient cycling.

Ecosystem services An ecosystem process that is beneficial for human beings, for example, the provision of foods and materials, sequestration of carbon dioxide, and stabilization of soils.

Factorial design Involves all possible combinations of the levels of the crossed experimental factors (fully factorial) or an incomplete but informative combination of levels (fractional factorial).

Functional group A group of species thought to have similar impacts on ecosystem functioning (functional effect groups).

Biodiversity Experiments

Biodiversity experiments aim to identify the consequences of changes in diversity for ecosystem functioning and services (as opposed to looking at the covariation of these two factors in comparative analyses of observational datasets). In the early 1990s, ecologists began formulating a set of hypothetical relationships between biodiversity and ecosystem functioning. These hypotheses ranged from those that implied a strong relationship in which the species are complementary and all play an important role, to those that include differing degrees of functional redundancy (species that overlap in functional role) to a null hypothesis of no link. In the early 1990s, these hypotheses were untested and the relationship between biodiversity and ecosystem functioning unknown. The subsequent years have seen a succession of experiments designed to test the effect of biodiversity on ecosystem functioning (Hooper *et al.*, 2005; Kinzig *et al.*, 2002; Loreau *et al.*, 2001, 2002). These experiments have revealed significant effects of biodiversity on ecosystem processes likely to affect the delivery of ecosystem services to human societies.

There are two main ways to manipulate biodiversity. One is by the assembly of synthesized model communities, either in laboratory cultures or in the field using artificial ponds or streams, forest plantations, plots in grasslands and similar experimental systems. An alternative approach is to remove species from natural communities, through weeding and herbiciding of plant species for example (Wardle *et al.*, 1999; Wardle and Zackrisson, 2005). Both approaches have strengths and weaknesses but both approaches attempt to hold other factors as constant as possible while manipulating the diversity of the experimental systems. A third nonmanipulative approach is to infer the relationship between biodiversity and ecosystem functioning by seeing how they are correlated across habitats.

Removal experiments are more familiar as they have a history of use in community ecology to examine interactions

between species (principally competition). They are more realistic than assembly experiments in that they are based in real ecosystems. However, increased realism comes at the price of a loss of control through potential unknown confounding factors. The approach also has its own potential limitations through the disturbance involved in species removal and other effects like fertilization through the decay of roots left behind after species removal.

The design and analysis of biodiversity experiments is not straightforward (Schmid *et al.*, 2002). One problem is the substantial levels of diversity present in most systems, which means that the number of possible experimental combinations soon exceeds what is logistically possible and fully factorial designs are only feasible when dealing with very small numbers of species. One way around this is to combine species into a small number of functional groups—species that are expected to have similar effects on ecosystem functioning. However, functional diversity may not fall into discrete groups and objectively identifying these groups is also not straightforward, leading to the development of approaches for looking at continuous measures of functional diversity (Petchey and Gaston, 2006). A second problem is that different aspects of diversity, such as numbers of species and functional groups, are often confounded. The combination of confounded explanatory variables and nonorthogonal designs has made it hard to definitively identify the importance of different aspects of diversity and the mechanisms by which they affect ecosystem functioning.

A further issue for community assembly experiments is how communities should be put together since the diversity gradient formed by the synthesized communities effectively simulates the assumed order of species loss. One approach is to assemble a full community and depauperate versions that simulate a single order of species loss. An alternative approach that provides a more general result is to replicate multiple communities of a given diversity by random selection of

species from the pool available. However, species are not usually lost from ecosystems in random order (although random loss may approximate some real-world cases). Instead, when a given extinction scenario can be predicted, communities can be assembled to simulate it. Alternatively, a fully factorial approach simulates all possible combinations of species but is limited by logistics to small numbers of species (or more often functional groups). Community assembly experiments should give a high level of experimental control but with the usual trade-off with realism. For example, establishment of the assembled communities usually involves removing any existing vegetation and surviving propagules and the disturbance that involves, e.g., soil fumigation. Homogenization of the underlying substrate should reduce the experimental noise, but may also remove environmental heterogeneity that affects the relationship between diversity and functioning.

To date, no one had conducted the same biodiversity manipulation in a given system using both species removal and the assembly of experimental communities and compared the results of the two alternative approaches. Similar results would provide strong support for general effects regardless of experimental methodology. Differences in results could be due to artifacts of the methodology but could also reflect important biological processes. For example, in removal experiments species compensation depends in part on natural levels of colonization of the newly free space, whereas community assembly experiments usually introduce equal numbers of propagules of all species as part of the method.

Ecological experiments can be large scale in different ways as this article illustrates specifically for biodiversity manipulations. Natural experiments may use only a single experimental unit but of a very large size: whole lakes or forest catchments for example. Alternatively, experiments may use a level of replication which is not especially large (a sample size of 30 for example) but where individual experimental units are of a size large for the study system (e.g., fields-scale trials with genetically modified crop species). Other large-scale projects use experimental units of conventional size but in complex and highly replicated designs. Multisite studies can be large if they combine experiments from several locations into a single coordinated project. Long-term studies are relatively unusual but can be of great value, and are large scale in a temporal context.

Mechanisms

Ecological theory identifies two classes of underlying mechanism that can generate impacts on ecosystem processes when diversity changes. Species influence ecosystem processes partly through their intrinsic properties. Whether a species with relatively extreme traits is present or absent from a system is one simple mechanism for impacts of biodiversity change. When species overlap in their ecological traits they are said to be redundant. When redundant species can compensate for the loss of similar species within the same group there will be little if any change in functioning. The redundancy can nevertheless be seen to have value as an ecological insurance. Conversely, when species occupy clearly distinct and

complementary niches it will be impossible for full compensation to occur. The degree of niche overlap should control the shape of the relationship between increasing diversity and ecosystem processes; low niche overlap will produce linear patterns while high overlap will lead to saturating curves as the addition of new species increases redundancy.

The interpretation of biodiversity experiments is complicated by these alternative classes of mechanism. Selection effects (Loreau and Hector, 2001) occur when communities become dominated by particular species and if dominant species occur more frequently in high-diversity communities then the traits of these species may drive ecosystem functioning. Alternatively, complementary or positive interactions may allow diverse systems to utilize more resources or to suffer lower levels of pests and diseases. An additive partitioning method (Loreau and Hector, 2001) was developed as part of the BIODDEPTH project (see below) to distinguish between these alternative mechanisms. The additive partitioning method (Loreau and Hector, 2001) defines a net effect of biodiversity which is the difference between the observed yield of a mixture and that of the average monoculture yield. This net effect is then partitioned into two additive components: the selection and complementarity effects. The selection effect is the standard statistical measure of covariance applied to the relationship between yield in monoculture and the change in relative yield in mixture. Selection effects will be positive when species with higher-than-average yield dominate communities and negative when species with lower-than-average yield dominate. The complementarity effect uses relative yields to ask whether increases in the abundance of some species exactly cancel with declines in others. When this is the case, resource partitioning is a zero-sum game with some species taking more of a fixed total pool of resources and others taking less. Positive complementarity effects occur when decreases in the abundances of some species do not compensate for the increases in the abundance of other species, which could result from facilitation, resource partitioning, or decreased impact of natural enemies in more diverse communities. The additive partitioning method has revealed widespread complementarity contributing to most published results. However, unanticipated negative selection effects have also emerged as a widespread result. One consequence is that complementarity effects are often masked by the negative selection.

Community Assembly

Historical Precedents

The intellectual linkage of biodiversity with ecosystem functioning can be traced back to the *Origin of Species* where Darwin describes what is arguably one of the first ecological experiments: a large-scale experimental garden comparing the properties of plant monocultures and mixtures (Hector and Hooper, 2002). Interestingly, the results prefigure those of recent experiments in associating higher levels of diversity with higher levels of biomass production (Figure 1). However, this early work inevitably lacks features of modern experimental design such as replication (in this experiment diversity was confounded with the origin of the experimental

Figure 1 Recently rediscovered data dating to the early nineteenth century which was collected from a large-scale experimental garden at Woburn Abbey, UK has many similarities to modern biodiversity experiments and is arguably some of the earliest experimental work conducted in ecology. Graph by A. Hector.

communities; that is whether they were transplanted natural turfs or established from seed).

The Ecotron Large-Scale Controlled Environment Facility

The first modern biodiversity experiment was carried out with model communities based on annual plant species grown in the Ecotron large-scale controlled environment facility (Naeem *et al.*, 1994). Most first-generation biodiversity experiments concentrated on a single trophic level. The Ecotron experiment was unusual in taking a single intact community and simultaneously reducing diversity at four trophic levels to produce two increasingly depauperate versions from which species had been omitted at random. The key result of this experiment was that the impoverished communities were progressively less productive. However, because all replicates at each diversity level were identical in composition, the effects of numbers and types of species were confounded and the results may be specific to the particular order of species extinction examined in this experiment and not general across a wider range of possible extinction scenarios.

Large-Scale Field Experiments

The first large-scale biodiversity experiments performed under field conditions were a series of studies by Tilman and colleagues working at Cedar Creek, Minnesota prairie grassland. A pair of biodiversity experiments concentrated on species (Tilman *et al.*, 1996) and functional group effects (Tilman *et al.*, 1997, 2001, 2006), respectively while the Biocon experiment (Reich *et al.*, 2001, 2004) looks at the interactions between biodiversity loss and elevated CO₂ and nitrogen. In contrast to the Ecotron experiment, more extensive diversity gradients were established where each level of diversity (a given number of species) was replicated with different mixtures of species selected at random from the species pool. Biodiversity effects could then be quantified with linear regression and tested against the residual differences between different composition communities within diversity levels. Productivity was positively related to numbers of species and

Figure 2 Greater temporal stability of biomass production in higher diversity communities from the first decade of the Cedar Creek prairie grassland experiment. Reproduced from Tilman D, Reich PB, and Knops J (2006) Biodiversity and ecosystem stability in a decade-long grassland experiment. *Nature* 441: 629–632, with permission from Nature Publishing Group.

functional groups in the communities with relationships growing stronger over several years. Levels of unconsumed soil nitrate and (potentially leachable) nitrate below the rooting zone were both reduced at higher diversity levels. Detecting how many species contribute to biodiversity relationships has proved one of the most contentious issues in interpreting biodiversity experiments. Tilman *et al.* (2001) used a diversity index approach to see how many of the most productive species in a plot had to be present to best explain their aboveground and total biomass production. For these two ecosystem processes between one quarter and three quarters, respectively, of the species in the high-diversity treatment were needed to best explain the productivity of a plot. Additional analyses of species-specific contributions suggest that much of the biodiversity effects can be explained by legumes and C₄ grasses but with additional species coexisting alongside them and contributing to total productivity (Lambers *et al.*, 2004). In contrast, in the Biocon experiment, which examined a biodiversity gradient under different conditions of elevated CO₂ and N enrichment, species and functional group richness had largely independent effects across the whole range of conditions such that species within groups were not functionally redundant but made separate contributions (Reich *et al.*, 2004).

A decade of monitoring of the Cedar Creek species and functional group diversity experiment confirmed the insurance hypothesis which predicts that biodiversity promotes greater temporal stability of ecosystem functioning (Figure 2). The highest diversity plots had a temporal stability measure (mean/standard deviation for a given time period) for biomass production that was 70% greater than the average of the monocultures. Greater temporal stability was generated by the portfolio effect (statistical averaging of asynchronous population fluctuations) and overyielding (where the yield of a mixture exceeds the weighted average of the constituent monocultures). Temporal stability at the ecosystem level was

positively correlated with high root biomass but, interestingly, negatively correlated with the presence of legumes (even though they promote overyielding in this system).

The Jena Biodiversity Experiment (Roscher *et al.*, 2004) simultaneously manipulates numbers of both species and functional groups in a randomized design but in a more balanced way than earlier experiments and in small (3.5×3.5 m) and large (20×20 m) plots (Figure 3). The project also contains a dominance experiment comprising plots composed only from a reduced pool of nine species predicted to be dominant (high relative abundance) in the full community.

Initial results from the Jena main experiment show that relationships from small plots can be scaled up to the large plots: results from the small and large plots were statistically indistinguishable. Productivity was positively linearly related to the log of the number of plant species. The slope of the relationship between diversity and productivity in the dominance experiment was statistically parallel to that from the fully randomized experiment but with a higher elevation (Figure 4). This results presumably because the average biomass production per species in the dominance experiment is higher than in the main experiment where species were chosen at random from the species pool which contains many species with low maximum aboveground biomass. Comprehensive results on the role of plant functional groups are yet to be published at the time of writing (summer 2006).

Multisite Biodiversity Experiments

The European BIODEPTH project (Hector *et al.*, 1999; Spehn *et al.*, 2005) added two new features to the single-site experiments described above. First, in addition to replicating diversity levels with different species compositions, each composition was itself replicated which allowed the effects of both diversity and composition to be quantified. Second, the same biodiversity experiment was replicated at eight different grassland sites using standardized methodologies. Individual

site analyses illustrate the broader range of responses seen in the literature—from null to positive—and the combined multisite analysis revealed an overall log-linear (asymptotic with increasing diversity) relationship that was statistically common to all sites. Reconciling the results of the individual site analyses with the general outcome of the overall analysis has been a point of both confusion and contention. The results of the BIODEPTH project also revealed that productivity could be well explained in terms of the multiple influences of location ($\sim 30\%$ of the total sums of squares), the diversity of both species and functional groups ($\sim 20\%$), and composition ($\sim 40\%$). Later results revealed that the effects of biodiversity were not limited only to aboveground biomass production but extended to a wider suite of ecosystem processes and properties including root biomass, levels of intercepted light, nitrogen pools in aboveground vegetation, and available soil nitrogen as well as the decomposition of various substrates. However, the relationship of some of these variables to biodiversity was often more complex and less clear than that of aboveground biomass production (Spehn *et al.*, 2005).

Other multisite experiments have been performed in terrestrial systems (e.g., Van der Putten *et al.*, 2000) but relatively few in aquatic and marine systems. A notable exception is the study by Emmerson *et al.* (2001) who examined the relationship between biodiversity and ecosystem functioning at multiple sites in the United Kingdom, Sweden, and South Australia. They looked at the relationship between the diversity of marine benthic faunal communities (ranging between 1–4 dominant species and 1–3 functional groups) and the production of nitrogen in ammonia form ($\text{NH}_4\text{-N}$) as an indicator of ecosystem functioning. Nitrogen production increased with community total biomass but for a given biomass production varied depending on the make up of the community. However, alongside this variation there were positive trends for greater predictability in ecosystem functioning at higher levels of diversity and a greater degree of complementarity between species in more diverse mixtures. In light of

Figure 3 The Jena Biodiversity Experiment manipulates numbers of species and functional groups in small (3.5×3.5 m) and large (20×20 m) plots. Photo by A. Klein.

Figure 4 The relationship between diversity and biomass production in the second year of the Jena Biodiversity Experiment. Results from the small and large plots are statistically indistinguishable and the relationship in the dominance experiment has the same slope but with a higher elevation. Graph by J. Schumacher.

this combination of species identity and species number effects Emmerson *et al.* characterized the relationship between biodiversity and ecosystem functioning in these marine systems as positive but idiosyncratic.

Highly Replicated Laboratory Experiments with Microbial Microcosms

In response to the complexities in the analysis and interpretation of biodiversity experiments, Bell *et al.* (2005) used a highly replicated laboratory experiment with a novel design to test whether the relationship between biodiversity and ecosystem functioning found for terrestrial plant communities extended to microbial microcosms. They took a pool of 72 laboratory culturable bacterial species isolated from the communities that develop in tree holes (the pools of water that collect between the exposed roots of trees at the base of their trunks). They took all the factors of 72 as their diversity levels (1, 2, 3, 4, 6, 8, 9, 12, 18, 24, 36, and 72) and replicated each level by drawing species from the pool without replacement. Five independent diversity gradients were formed in this way to give five alternative partitions of the species pool. Finally, each particular partition was repeated twice to provide compositional replication (a feature first introduced by the BIODDEPTH experiment; see below). In total, the experiment required 1374 microbial microcosms. This novel approach resulted in an analysis where the log-linear effect of species richness (numbers of species on a log-scale) was orthogonal to the effect of species composition (the collective effects of 72 variables coding for the presence or absence of each species in each microcosm). The main result was a log-linear relationship between diversity and community respiration (Figure 5), which was similar to the relationship between diversity and biomass production in experiments with plants. The independence of the log-linear diversity effect from the composition effect, combined with only a small number of strong individual species effects suggests that the result was not produced by dominance of the microbial communities by species with high respiration rates but more likely resulted

from complementary or facilitatory relationships or a combination of the two.

Species Removal

Wardle and Zackrisson (2005) used a series of islands in a Swedish lake as a study system to examine influences on ecosystem functioning. The island system allowed them to look at patterns when comparing across the habitats (islands) as well as to perform removal experiments within individual systems. These islands show varying diversities and ecosystem process rates due to their size and likelihood of disturbance. Large islands are more prone to fires caused by lightning strike and therefore experience higher levels of disturbance and have lower diversity (species richness is the same on all islands but diversity varies once differences in relative abundance, or “evenness,” is taken into account). Note that this relationship is contrary to the predictions of classical island biogeographic theory, which ignores many processes like disturbance. Productivity is greatest on the large, more frequently disturbed islands, and therefore negatively related to diversity (Figure 6a). The smaller, low-productivity islands tend to be dominated by “stress-tolerant” species (*sensu* Grime, 2001) and have lower levels of decomposition and related processes as well as lower productivity. Wardle and Zackrisson (2005) supplemented the across-island comparison by performing manipulative experiments to remove species and functional groups from a subset of the islands of differing sizes. Despite the negative correlation between diversity and process rates across islands, the removal experiments showed significant impacts of the removal of three species of shrub on productivity (Figure 6b). Two of the species showed larger removal effects on islands where they were more abundant. This study demonstrates scale-dependence of the relationship between diversity and functioning and how manipulative experiments can reveal diversity effects within systems (positive in this case) which can differ from the larger-scale across-site correlation (which was negative in this study).

In an earlier removal experiment that manipulated the functional group composition of vegetation gaps in a New Zealand pasture grassland, Wardle *et al.* (1999) found some impacts on both above- and belowground processes. However, whether an effect was found and how strong it was depended on the traits of the species that were experimentally excluded. Similarly, in the same Cedar Creek prairie that hosted the community assembly experiments reported above, removal of plant functional groups also negatively affected above- and belowground biomass, soil nitrogen, and drought resistance but where the effects related to which group was removed and to the response of the remaining functional groups (Symstad and Tilman, 2001). Removal of plant functional groups often also facilitated invasion by other species (Symstad, 2000). Many of the results of this and other removal experiments are related to recruitment limitation, a process that is not as evident in community assembly experiments owing to the seed addition used to establish communities.

Utilizing Biodiversity in Applied Settings

The large-scale biodiversity experiments described above all come from pure ecology and aim to identify generalities in the relationship between biodiversity and ecosystem functioning in various types of ecosystem. However, in the real world, biodiversity is lost due to specific processes (eutrophication, fragmentation, and overharvesting) and in some cases pure studies may not give general predictions which apply to particular real-world cases. A small number of applied experiments have been established to see whether biodiversity can

Figure 7 Increases in hay production through the augmentation of agriculturally recommended seed mixtures with additional species. Reproduced from Bullock JM, Pywell RF, Burke MJW, and Walker KJ (2001) Restoration of biodiversity enhances agricultural production. *Ecol. Lett.* 4: 185–189.

be used in the management of habitats in a way which is beneficial to the provision of ecosystem services to humans.

Grassland Restoration

Bullock *et al.* (2001) performed a biodiversity experiment on the restoration of hay meadows at seven locations across southern Britain. At each site, plots were sown with “low-diversity” treatments (6–17 species depending on the site) which consisted of the seed mixtures recommended by the (then) UK Ministry for Agriculture Fisheries and Food (MAFF) for the recreation of moderately diverse grassland on land taken out of agricultural production. The recommended seed mixtures were all composed of species from the relevant regional species pool, which were also appropriate for the type of local environment to be restored. The “high-diversity” treatments (25–41 species) were supplemented with species found in diverse hay meadows typical of the region, soils, and hydrology of each site. The high-diversity mixtures therefore contained species appropriate for each site but which had been omitted from the recommended mixture and which were therefore presumably thought to be redundant for restoration purposes. The key result was a linear relationship between hay yield and the number of additional species added to the high-diversity treatments which was consistent across all sites and present for three years after the initial establishment season (Figure 7). The selection of a wider diversity of species increased yield by up to 60%. For all the seven sites, the seed mixtures thought to be sufficient for restoration aims led to levels of hay production which were far below those achievable at the same site by more diverse mixtures that contained a wider selection of appropriate species. The increase in yield seemed not to be due to sampling or selection effects for one or a few dominant species although rigorous testing of the underlying mechanisms was not possible without monocultures of all species involved.

Tree Diversity Experiments

Forest ecosystems, particularly in the tropics, are important both for the conservation of biodiversity and the provision

of important ecosystem services but little is known about the relationship between forest biodiversity and ecosystem functioning. Forest ecosystems around the globe that have previously been clear felled or selectively logged are being replanted providing an opportunity to test the importance of restoring levels of biodiversity for the functioning of the rehabilitated ecosystems. There is now an informal network of forest biodiversity experiments that currently ranges from the neotropics (Panama) through Europe (Finland, Germany) to the paleotropics (Malaysian Borneo) as described by Scherer-Lorenzen *et al.* (2005). These experiments signal a new direction in research on biodiversity and ecosystem functioning which moves beyond general tests to large-scale trials in threatened ecosystems that are known to provide important ecosystem services to mankind.

Phenological Shifts in Animals Under Contemporary Climate Change

Marcel E Visser, Netherlands Institute of Ecology, The Netherlands

© 2013 Elsevier Inc. All rights reserved.

Glossary

Circannual rhythms Recurrence of a phenomenon in cycles of approximately 1 year.

Phenological shifts Change over years in the mean of the phenological value of a trait within a population.

Phenology The study of the seasonal timing of natural events, such as the return date of migrant birds or the initiation of reproduction.

Phenotypic plasticity The plasticity of a genotype to express a different phenotype under different environmental conditions.

Reaction norm The relationship between the phenotypic expression of a single genotype and the environmental conditions under which the phenotype is shaped.

Introduction

Over the past three decades, global climate change has had a clear impact on the biology of wild species. One of the most pronounced effects has been on the phenology, or seasonal timing, of species. There are numerous examples of animal and plant species that have shifted their phenology to an earlier date in spring, such as the return date of avian migrants, the termination of hibernation periods, or the hatching date of overwintering insects. Before summarizing these observed shifts in animal species, the article first discusses a general framework for phenology, which can be used to understand why phenology is likely to be affected by climate change and the mechanisms by which this may occur.

Animals go through distinct annual life-history cycles. There are times of the year when they reproduce, times when they molt their feathers or change their coat, and times when they hibernate or migrate to overwintering areas. These life history stages often have a strict order and happen at relatively fixed periods within a year: In harsh winter, marmots hibernate, and in spring, when food is plentiful, they have their offspring. This annual life history cycle is tuned to the variation in environmental conditions: The most demanding life history stages have to match the times within a year when the environment is most favorable. As the timing of these favorable periods often varies from year to year, so too does the phenology of the life cycle: In some years, migrant birds return earlier to their breeding grounds than in other years, and ultimately this will be because favorable conditions occur at different times in different years.

Phenological phenomena are studied by different biological disciplines, which differ in their approaches and in questions investigated (Visser *et al.*, 2010). Phenology research as a discipline observes the periodic appearance of life cycle events and relates their annual variation to the variation in climate. Many of the reports on shifts in phenology simply regress the mean annual value of the phenology of a trait against mean temperature over a specific period and demonstrate that this mean date is, for example, earlier at higher spring temperatures. But phenology is also studied by evolutionary ecologists, who term it “seasonal timing” and emphasize the variation in timing among individuals and its

fitness consequences. Phenology as it is studied by chronobiologists is viewed as the periodic nature of life cycle stages with an emphasis on their underlying endogenous timing programs (the so-called circannual rhythms). Finally, on a more mechanistic level, the (neuro-)endocrine processes underlying these life cycle events are studied by physiologists, and these processes are linked to genes by molecular geneticists (see Visser *et al.*, 2010 for a full discussion on an integrated framework of these disciplines). This article will apply the framework used by evolutionary ecologists as this will help explain, rather than just describe, the patterns in the observed shifts in phenology due to climate change.

Conceptual Framework for Shifts in Phenology

Animals have evolved seasonal patterns of activity that allow them to match their energetic needs, or that of their offspring, with the temporal pattern in environmental conditions. To optimize the annual scheduling of reproduction, migration, hibernation, etc., animals use photoperiod (i.e., day length, a reliable indicator of time of year) to anticipate seasonal changes in conditions. Photoperiod does not vary from year to year, however, so it cannot account for year-to-year variation in phenology (Bradshaw and Holzapfel, 2006). In the temperate zones, temporal changes in the environment are closely related to changes in temperature. In a warm spring, for instance, trees develop their leaves early and thus insects that feed from these newly developed leaves also need to appear early. For this reason, many temperate zone species use temperature as a cue: Their phenology is causally affected by temperature or by an environmental variable closely associated with temperature. Note, however, that in some species, for example, those inhabiting desert environments, their relevant environmental variation might be affected by variables other than temperature. For instance, variation in food abundance for zebra finches is more strongly affected by rainfall than by temperature, and thus environmental variables associated with rainfall are used instead (Zann *et al.*, 1995).

The relationship between phenology and temperature is mainly caused by individuals that change their phenology via

a mechanism termed “phenotypic plasticity” (Pigliucci, 2001): the same genotype (individual) expresses a different phenotype (phenological trait) under different environmental conditions (spring temperatures). The relationship between the phenological trait and the environmental variable affecting its value is termed a “reaction norm.” Thus, the often observed negative relationship between a phenological trait and the temperature for a population is the result of individual reaction norms; for example, individuals respond by breeding earlier in warmer springs. Note, however, that there may be significant individual variation in the steepness (Nussey *et al.*, 2005) or shape (Reed *et al.*, 2009) of these reaction norms within a population although this is not always the case (Charmantier *et al.*, 2008; Reed *et al.*, 2006), with the response at the population level being the combined effect of all individual responses.

Climate change has led to a clear increase in mean temperatures worldwide; however, with striking variation both spatially (in some parts of the world, temperatures have increased more than in other parts) and temporally (within a single location, temperatures have increased more acutely in some parts of the year than in other parts). This increase in ambient temperature will, for the majority of species, shift their phenology to an earlier date in the year, because most species use temperature or a temperature-related environmental variable as a cue. Whereas among vertebrates, temperature may affect phenology mainly because it is used as a cue, for insects, temperature may (also) play a more direct role as the rate of many developmental processes in ectothermic species is temperature dependent. Global warming will thus directly affect the phenology of insects’ life cycles, such as egg hatching date, when temperatures in the period after breaking diapause increase.

Methodological Issues in Studying Shifts in Phenology

Many studies have estimated shifts in phenology over recent decades. Before addressing these, however, it is useful to discuss a few methodological issues related to these estimates. One of the main methodological problems is that many datasets used to estimate phenological shifts are based on the first observations of an event: The first birds of a certain species returning from their wintering areas, the first butterfly seen in spring, etc. In a methodological paper, Moussus *et al.* (2010) used simulated data to compare 10 phenological estimators and found that first event dates are an inaccurate and biased estimator for the phenology of entire populations. This result was confirmed empirically in a few studies for which the entire distribution of phenological events was available. These show that first events shift more rapidly than middle or peak events (Miller-Rushing *et al.*, 2008; van Buskirk *et al.*, 2009; Thackeray *et al.*, 2010).

A second potential methodological problem is the strong increase in amateur observers, who have collected most of the long-term data on plants, birds, and butterflies, over the past decades. The date of first events, in particular, is strongly affected by the number of observers, and as a result, shifts in phenology might reflect the increased probability of observing a phenological event rather than a real change in the

phenology of a species. This problem is also best solved by directing efforts to measure the entire distribution of phenological events rather than observing first events only (Moussus *et al.*, 2010).

A third methodological problem is also related to observing first events. With an increasing population size, it is likely that the date of first event shifts forward. This was shown by Tryjanowski and Sparks (2001), who analyzed migration phenology of red-backed shrike (*Lanius collurio*) in Poland from 1983 to 2000. The red-backed shrike both returned earlier and increased in population size, and a further analysis showed that there was a negative correlation between arrival phenology (Julian date of arrival) and population size. Another example comes from a study of 32 migratory North American bird species (1970–2002), which showed that changes in first arrival date differed strongly from changes in mean arrival date (0.2 days per decade later vs. 0.8 days per decade earlier). The difference in these two trends was due to declining cohort sizes over time (Miller-Rushing *et al.*, 2008). Thus, reports on shifts in phenology in first events need to take population increases or decreases into account, although this is seldom done.

A final pitfall is publication bias. Meta-analyses including single-species studies, in particular, may be a potential problem as positive results are more likely to be published than no change (Parmesan, 2007). Such a positive publication bias will lead to estimates of shifts based on datasets that under-represent taxa showing little or no phenological change (Thackeray *et al.*, 2010). One way to prevent a publication bias is to use in meta-analyses only multispecies studies that report data on both shifting and nonshifting species (Parmesan and Yohe, 2003).

Observed Phenological Shifts Under Climate Change

There is an overwhelming body of literature on shifts in phenology in response to climate change. This article first presents an overview of the general review papers and then discusses some trends that emerge from these reviews. Next is a discussion on the variation in phenological shift among species within taxonomic groups and variation among populations within species.

General Reviews

The first two general reviews on the shift in phenology in response to climate change were published in 2003: the paper by Parmesan and Yohe (2003) and by Root *et al.* (2003) both reviewed the peer-reviewed literature, but their selection criteria for inclusion of studies differed. Although in both cases the overall conclusion was that there were clear shifts in phenology, the estimates of the magnitude of this shift differed: Parmesan and Yohe (2003) estimated the shift to be 2.3 days per decade across all species, whereas Root *et al.* (2003) calculated a shift of 5.1 days per decade for the subset of species showing a shift of at least 1 day per decade. The two papers were explicitly compared by Parmesan (2007), who attributed the difference in these shifts to the criteria used:

Figure 1 Shifts in spring phenology (days per decade) for individual species grouped by taxonomy or functional type. Each bar represents a separate, independent species. Negative values indicate a shift toward earlier phenology over time, positive values a shift toward later phenology (reproduced from Parmesan C (2007) Influences of species, latitudes and methodologies on estimates of phenological response to global warming. *Global Change Biology* 13: 1860–1872, with permission from Wiley).

Root *et al.* (2003) used both single species as well as multi-species studies and included only studies in which the shift was larger than 1 day per decade, whereas Parmesan and Yohe (2003) used only multispecies studies, independent of whether species shifted phenology or not. To obtain a better estimate for the shift in phenology and the variation in this shift among taxonomic groups, Parmesan (2007) used a combined data set of 203 Northern Hemisphere species in which only a single data point for each species was included. Using this combined database, the best estimate for the shift in spring phenology was 2.8 days per decade. However, there is substantial taxonomic variation in this rate: The shifts in phenology in amphibians were more than twice that in trees, birds, and butterflies, and almost eight times as fast as in herbs, grasses, and shrubs (Figure 1).

Thackeray *et al.* (2010) analyzed the phenological shifts in 726 terrestrial, freshwater, and marine species in the UK. They compiled more than 25,000 shifts calculated from the raw observations from 18 UK monitoring programs for a period of 30 years. Their estimate across taxonomic groups was a shift of 3.9 days per decade and with 84% of the observed shifts toward an earlier seasonal timing. This shift is somewhat higher than the shift of 2.8 days per decade estimated by Parmesan (2007). This may be either due to the time period used (1976–2005) by Thackeray *et al.* (2010), a period in which climate change was more pronounced, or due to the difference in the geographical region: In the UK data set used by Thackeray *et al.* (2010), shifts in phenology may be stronger than in the rest of the Northern Hemisphere data set used by Parmesan (2007). Like Parmesan (2007), Thackeray *et al.* (2010) also found large differences in the phenological shift among species from different taxonomic groups (Figure 2). Terrestrial plants shifted the most, whereas freshwater plant species shifted the least. Terrestrial invertebrates shifted more (4.1 days per decade) than terrestrial vertebrates (2.6 days per decade).

A few more general reviews have been published, albeit more limited in taxonomic diversity or geographical range

(Walther *et al.*, 2002; Menzel *et al.*, 2006; Penuelas *et al.*, 2002). Menzel *et al.* (2006) presented phenological shifts from 21 European countries for the period 1971–2000, using national schemes with standardized datasets, but although data on 19 animal species were available, they report only on the data for the 542 plant species. Penuelas *et al.* (2002) studied phenological shifts in plants and arrival dates of birds in the Mediterranean region with the surprising result that the plants advanced their bud burst, flowering, and fruiting, but the sub-Saharan migratory birds now arrive 15 days later than in 1950.

From these reviews, a number of general conclusions can be drawn. First, there is a very clear shift in phenology toward an earlier date in response to climate change of between 3 and 4 days per decade, and second, that species from different taxonomic groups shift at different rates. However, these conclusions are to a very large extent based on data from the Northern Hemisphere. What little data there are from the Southern Hemisphere seem to point in a different direction. For instance, Barbraud and Weimerskirch (2006) show that for nine seabird species breeding in the Antarctic, both the breeding and the migratory phenology have shifted to later dates over the period 1950–2004. The overall shifts indicated that birds arrive 1.7 days per decade later and lay eggs 0.4 days per decade later. Another limitation of the data is that the majority of the documented shifts concern spring phenology. There are a few documented autumn shifts that show a shift in phenology to a later date such as leaf fall dates (Penuelas *et al.*, 2002) and the date of autumn migration in birds (Jenni and Kéry, 2003; Lehikoinen *et al.*, 2004).

Between-Species Variation Within Taxonomic Groups

There are a number of review papers on specific taxonomic groups, most of them on laying date in birds (Dunn, 2004; Crick *et al.*, 1997; Crick and Sparks, 1999). The first of these

Figure 2 Phenological shifts from 1976 to 2005 for UK plants/phytoplankton (green), invertebrates (yellow), and vertebrates (blue) in marine, freshwater, and terrestrial environments. Negative values indicate a shift toward earlier phenology over time (reproduced from Thackeray SJ, Sparks TH, Frederiksen M, *et al.* (2010) Trophic level asynchrony in rates of phenological change for marine, freshwater and terrestrial environments. *Global Change Biology* 16: 3304–3313, with permission from Wiley).

was by Crick *et al.* (1997), who analyzed laying date from more than 74,000 nest records from 65 bird species from the UK between 1971 and 1995. In 51 of these species, there was a trend toward earlier nesting, with an average advancement of 3.5 days per decade for the 20 species for which the shift in phenology was significant, whereas just a single species, the stock dove (*Columba oenas*), laid significantly later. In a follow-up paper on an extended data set for the period 1939–1995, Crick and Sparks (1999) found that 19 out of 36 species showed an advance of laying date over the period 1970–1995. Dunn (2004) brought together data on shifts in the phenology of laying dates or hatch dates for an additional eight species from various locations, and in all of these, there is evidence for a shift to an earlier date.

These overviews of avian reproductive phenology thus clearly show that phenology has shifted, but perhaps more strikingly, they demonstrate a large variation in the rate of the shifts between species within a taxonomic group, even within a single geographic location (as in the Crick *et al.*, 1997, study). There are two potential explanations for this variation: Either the magnitude at which temperature is increasing varies among species' distribution ranges or species vary in their sensitivity to temperature. As there is certainly variation in the phenological shift among species at the same location, the latter explanation is more likely. The conceptual framework for the shifts in phenology (see Conceptual Framework for Shifts in Phenology) also predicts variation in temperature sensitivity among species. The sensitivity of a species to temperature, and thereby the rate at which its reproductive phenology will shift, will ultimately depend on the extent to which the phenology of its food depends on temperature (Visser and Both, 2005). The food phenology of some species is highly temperature sensitive, such as insectivorous forest passerines, whereas that of other species may not depend on temperature at all. This, for instance, explains why the

phenology of the stock dove (*C. oenas*) did not advance (Crick *et al.*, 1997) as this is a species that feeds its nestlings with milk from the crop-sac (Dawson *et al.*, 2001) and hence can feed on a wide range of food for which the phenology will not have changed. Other opportunistic breeders, like crossbills, are also not likely to advance their phenology if climate change leads to increased temperatures.

A number of overviews on the shifts in avian migration phenology make use of the banding stations along migratory flyways (Jenni and Kéry, 2003; Hüppop and Hüppop, 2003; Jonzen *et al.*, 2006; Sokolov, 2006; Lehikoinen *et al.*, 2004). Hüppop and Hüppop (2003) showed for 24 migratory species that they now pass through Helgoland (Germany) in spring 0.5–2.8 days per decade earlier than in 1960, with no difference between short/medium-distance and long-distance migrant species. In a study in Pennsylvania (USA), van Buskirk *et al.* (2009) found that spring migration advanced in a set of 58 songbird species over a 46-year period with on average 0.7 days per decade. In a meta-analysis of 21 studies recording first arrival dates of 983 species/study combinations, Lehikoinen *et al.* (2004) found an advancement of 3.7 days per decade, whereas a meta-analysis of five studies (with 222 species/study combinations) on median/mean migration time showed an advancement of 1.0 day per decade. Shifts in autumn migration have been documented less frequently and are often more variable (van Buskirk *et al.*, 2009). Jenni and Kéry (2003) show for 65 bird species that, over a 42-year period, birds passing through Switzerland altered their passage time. Although long-distance migrants pass through earlier in recent years, medium-distance migrants pass through later, especially the species that have multiple broods per year. For these species the breeding season has become prolonged as climate change has led to a longer period of favorable conditions. This study again shows that there may be large differences among species in their shifts in phenology, related to their ecology.

Another source of data on shifts in avian migratory phenology comes from studies on arrival dates (Cotton, 2003; Penuelas *et al.*, 2002; Gordo and Sanz, 2005). In the UK, a study on 20 migrant species showed an average advancement of 2.7 days per decade (Cotton, 2003). Arrival dates of 23 species of passerines at the Courland Spit (Russia) advanced in 22 species (15 significantly), an average of 3.8 days per decade, with no difference between median- and long-distance migrants (Sokolov, 2006). However, not all studies show an advancement of arrival date. In Spain, five out of six long-distance migrant species now arrive later rather than earlier over a 50-year period (Penuelas *et al.*, 2002). This again emphasizes the substantial variation across geographical scales, which for migratory birds is even more pronounced as it is the variation in climatic change not only in the breeding location but also in the overwintering location that contributes to the variation in the shift in phenology.

Butterflies are the only other taxonomic group of animals for which an overview of phenological shifts for a reasonable number of species is available (Roy and Sparks, 2000; Stefanescu *et al.*, 2003; Forister and Shapiro, 2003). In all these studies, the phenology of first appearance has advanced. In the UK, this was true for 26 out of 35 species, of which 13 were statistically significant (mean advancement over all species 3.7 days per decade; Roy and Sparks, 2000); in Spain, for all of the 17 species included in the study, of which five were statistically significant (Stefanescu *et al.*, 2003); and in California, 16 out of 23 species advanced their phenology, of which four were statistically significant (mean advancement over all species 1.7 days per decade; Forister and Shapiro, 2003). Despite the clear overall advancement in phenology over the past decades, butterflies also show clear among-species variation in the rate (and to a lesser extent the direction) of these shifts. Forister and Shapiro (2003) tested whether species that appear early in the season shifted more, which was not the case. However, species that overwinter as pupae did advance their phenology more than those overwintering as larvae.

Between-Population Variation Within Species

Comparisons of the shifts in breeding phenology among populations within species are quite rare as the comparisons depend on long-term studies of a single species at several locations. Data have been analyzed for four bird species, all hole-breeding passerines: great tit (*Parus major*), blue tit (*Cyanistes caeruleus*), pied flycatcher (*Ficedula hypoleuca*), and tree swallow (*Tachycineta bicolor*) (Sanz, 2002; Both *et al.*, 2004; Visser *et al.*, 2003; Dunn and Winkler, 1999; Sanz, 2003). Tree swallows advanced their laying date 2.7 days per decade over the period 1959–1991, based on an analysis over their entire North American breeding range (Dunn and Winkler, 1999). In a Europe-wide analysis of pied flycatchers, Both *et al.* (2004) focused on geographical variation in the shift in breeding phenology. They found that 9 out of the 23 study population significantly advanced their phenology in the period 1980–2002, with an average shift over all populations of 1.6 days per decade. More importantly, they showed that the rate of advancement was correlated with the rate at which temperature had increased at that location, again

emphasizing that the variation in the change in phenology is related to geographical variation in the change in climate. Visser *et al.* (2003) analyzed laying dates of 14 European populations of great and blue tits for 1979–1998 and also found that despite a general advancement in phenology (over all populations, advance for great tits was 3.1 days per decade and for blue tits 3.5 days per decade), there was ample variation among populations in the rate of change in breeding phenology. This variation was correlated with the degree to which populations were formerly double brooded: Populations that historically were single brooded advanced their laying dates more than those that used to be double brooded and have now become single brooded (Husby *et al.*, 2009). Thus, not only these within-species studies echo the results of among-species studies, showing that variation in the shift in phenology is correlated with geographical variation in change in climate, but the within-species variation in general life-histories also plays an important role.

Linking Observed Shifts in Phenology to Climate Change

This section discusses how shifts in phenology of three major phenological life history events – timing of reproduction, timing of migration, and timing of winter rest – are linked to climate change. There are two general approaches to linking phenology to climate change. The more common one is to correlate shifts in phenology to some measure of climate, often with local temperatures. In most studies, phenology is correlated with temperature by averaging temperature over some period. Although there are ample problems with this, (see Outlook), the author includes these studies as they form the bulk of the literature. Some studies correlate phenology with large-scale atmospheric phenomena, such as the North Atlantic Oscillation (NAO; Hurrell *et al.*, 2001) or the El Niño–Southern Oscillation (ENSO; Trenberth and Caron, 2000). Winter NAO, defined as the difference in the sea-level air pressure between Portugal and Iceland from December to March (Hurrell *et al.*, 2001), captures variation in climatic conditions on a large scale. In years with positive NAO values, weather in Europe is more affected by Atlantic influences, leading to wetter winters with higher temperatures, whereas in years with negative values the weather is more affected by continental influences, characterized by cold, dry winters in the north of Europe. The ENSO is characterized by variations in the surface temperature of the tropical eastern Pacific Ocean (of which the warming and cooling phases are known as El Niño and La Niña, respectively) and by air surface pressure in the tropical western Pacific (the Southern Oscillation). In years with positive anomalies, there are drier conditions in the Gulf of Guinea and Sahel rainfall is reduced. These large-scale atmospheric phenomena are used to correlate phenology with a set of climatic variables on a larger geographical scale, rather than with specific local temperatures. The atmospheric approach may be more appropriate when analyzing phenological data on larger scales or when trying to capture the effect of more climatic variables than temperature (Hallett *et al.*, 2004).

A second approach is to study, under controlled conditions, the environmental variables involved in the phenotypic plasticity of individuals, which underlies the changes in phenology. Although this approach allows for causal rather than correlational work, the number of species studied in sufficient detail to make the link between plasticity and phenological shifts is very limited, also because it turns out that causal links of phenology to temperatures are difficult to demonstrate in vertebrates (Visser *et al.*, 2009). This section therefore concentrates on the approach in which phenology is correlated with environmental variables, either as temperature or as NAO and ENSO, but returns to the latter approach in the section Outlook.

Timing of Reproduction

Shifts in the reproductive phenology (timing of reproduction) have been linked to temperatures for many taxonomic groups. For birds, Crick and Sparks (1999) showed that for 31 out of 36 species, the breeding phenology was correlated with temperature and precipitation. In the overview of Dunn (2004), in 50 out of 63 studies, temperature was correlated with laying date. An even more direct indication that shifts in laying dates are due to climate change comes from the correlation between the change in laying date and the change in local temperature in a Europe-wide comparative study of pied flycatchers (Both *et al.*, 2004). In four species of amphibians, there was also a clear correlation between spawning date and temperature (Beebe, 1995), which could account for the advancement of their phenology. In a mammalian species, the caribou (*Rangifer tarandus*), the timing of onset of calving was correlated with temperatures in the period from March to May (Post and Forchhammer, 2008). There is thus ample evidence that reproductive phenology is correlated with temperatures, albeit that the period over which these temperatures are averaged varies from species to species (see Outlook).

Using NAO rather than local temperatures, Sanz (2002) found that the breeding phenology of great and blue tits was correlated with winter NAO (with earlier laying at positive NAO values). A similar result was found by Forchhammer *et al.* (1998) for the corn bunting (*Miliaria calandra*) and the chiffchaff (*Phylloscopus collybita*), as well as for the spawning date of three species of amphibians.

Timing of Migration

One of the key problems with linking migration phenology to climatic conditions is that potential climatic conditions at the wintering grounds, the breeding grounds, and along the migration route all play a role (Gordo, 2007). There are ample studies showing a correlation between arrival or passage dates and local temperatures. In a meta-analysis on migratory birds, Lehikoinen *et al.* (2004) showed that both first arrival dates and median/mean migration phenology were negatively correlated with local temperatures. As these local temperatures cannot causally affect the birds at departure or *en route*, it is likely that, due to large-scale spatial autocorrelations in climate, the temperatures experienced by the birds at departure or *en route* were correlated with these local temperatures.

Given that migratory species are affected in their phenology by conditions on a larger spatial scale, many studies

have correlated migratory phenology with large-scale atmospheric phenomena, mainly with the NAO. In their meta-analysis, Lehikoinen *et al.* (2004) found a clear negative correlation between phenology and NAO, both for first date of arrival and for median/mean migration phenology. One of the studies in their meta-analysis, in which 40 years of observations on Helgoland (Germany) were analyzed, found that mean spring passage time for no less than 23 out of 24 birds species had a negative relationship with NAO (Hüppop and Hüppop, 2003). In another meta-analysis on avian migration phenology Gienapp *et al.* (2007) analyzed data from 18 studies on 249 species and also found a negative relationship between migration phenology and NAO, which did not differ for European long- and short-distance migrants.

Considerably fewer studies have correlated migration phenology with another large-scale atmospheric phenomenon, the ENSO. For instance, Barbraud and Weimerskirch (2006) related the breeding and the migration phenology of six bird species breeding in the Antarctic to ENSO, and in only one species, the Cape petrel (*Daption capense*), there was a significant correlation. MacMynowski and Root (2007) found a correlation between migratory phenology and ENSO for only 2 out of 22 North American species. Another study on 23 North American migrants showed that variation in arrival date of short-distance migrants correlated with variation in temperature, whereas for medium-distance migrants, a correlation was found with the Southern Oscillation Index (Miller-Rushing *et al.*, 2008).

Clearly, European and North American avian migratory phenology is correlated with both local temperatures and NAO. There is not much evidence for correlations with ENSO, but given that the overwhelming majority of studies are on Northern Hemisphere populations, clearly more data are needed. There is some evidence that the phenology of short-distance migrants correlates best with local temperature, whereas that of medium- or long-distance migrants is correlated better with the NAO (MacMynowski and Root, 2007; Miller-Rushing *et al.*, 2008). This would make sense if short-distance migrants overwinter so close enough to their breeding grounds that there is spatial autocorrelation in climatic conditions between their wintering and breeding areas. In long-distance migrants, autocorrelation is less likely, so that a large-scale atmospheric phenomenon, such as the NAO, captures the relevant climatic variables better.

For taxonomic groups other than birds, there are very few studies linking migration phenology to either temperatures or NAO, but there is some evidence that the migration phenology in veined squid (*Loligo forbesi*) is correlated with sea water temperature and with NAO (Sims *et al.*, 2001), and similar correlations were found for a fish, the flounder (*Platichthys flesus*) (Sims *et al.*, 2004). In pink salmon (*Oncorhynchus gorbuscha*) in Alaska, fry migration phenology advanced in response to increasing water temperatures 5.0 days per decade in the period 1972–2005 (Taylor, 2008).

Timing of Onset and Termination of Winter Rest

Many species have some sort of winter rest. Insects may go into diapause as an egg, a larva, a pupa, or an adult, whereas mammals may hibernate throughout the winter. Such a life

history requires two timing decisions: When to go into winter rest and when to become active again. In many species the induction and the breaking of diapause or the start and end of hibernation are triggered by photoperiod or by some internal clock. However, the developmental rate in, for instance, insect eggs is strongly affected by temperature, and hence the length of time until these eggs hatch will be directly related to temperature.

Adult winter moths (*Operophtera brumata*) enclose from their pupae in November/December, after which they mate and the wingless females lay their eggs on the branches of trees. These eggs then develop slowly until they hatch in April, at the time the buds of the trees open. The phenology of egg hatching is clearly affected by temperature, as shown both in the wild and under controlled conditions (Visser and Holleman, 2001), and thus egg hatching date has advanced due to climate change. Butterfly larvae come out of winter egg rest in spring, and their date of first appearance is correlated with spring temperatures. Many species thus have advanced their flight period as a consequence of climate change (Roy and Sparks, 2000; Stefanescu *et al.*, 2003; Forister and Shapiro, 2003).

Termination of hibernation of the yellow-bellied marmot (*Marmota flaviventris*) in the Colorado Rocky Mountains is strongly affected by April temperatures (Inouye *et al.*, 2000). As these temperatures increased, the marmots emerged 38 days earlier over the period 1975–1999 (15.2 days per decade).

Overall Conclusion

In all taxonomic groups there is clear evidence that the phenology of a majority of species is correlated with one or another temperature or, especially for migratory species, with large-scale climatic patterns. However, it is not always clear over which period predictive temperature needs to be averaged as this varies from species to species depending on their ecology. Additionally, correlating a phenological event with the mean temperature over a fixed period has clear methodological problems (*see Outlook*). Despite this general pattern there are also species whose phenology is not affected by temperature. These are likely species for which temperature does not predict the period of favorable conditions (*see Conceptual Framework for Shifts in Phenology*). Furthermore, for the few species for which this has been studied, temperature sensitivity of phenology varies on a geographical scale with populations at more northern locations being less temperature sensitive (Silverin *et al.*, 2008). Because climate change scenarios predict the strongest temperature changes in the north, this lack of sensitivity may lead to insufficient shifts in phenology in northern locations (*see Phenological Mismatches Due to Climate Change*).

Phenological Mismatches Due to Climate Change

Mismatches among Trophic Levels

Although many species shift their phenology in response to contemporary climate change, this does not mean that these shifts are necessarily adaptive, that is, that there are no negative effects on the reproductive success or survival of these

shifts. To determine whether the observed shifts in phenology are sufficiently compensatory, or perhaps even too strong, some kind of yardstick is needed. Visser and Both (2005) proposed to use the shift in phenology of the food of animals as such a yardstick. For instance, to assess whether small insectivorous birds shift their breeding phenology sufficiently, their rate of advancement is compared to the rate at which the phenology of their food source, caterpillars, is advancing. Of the 10 pairs of species interaction for which data on phenological shifts were available, in five the shift of the predator was not strong enough, in two cases it was too strong, and only in three cases the shifts of prey and predator were of similar strength (Visser and Both, 2005). Thus, in the majority of the cases, climate change has led to a so-called phenological mismatch (Visser *et al.*, 1998; Stenseth and Mysterud, 2002; van Asch and Visser, 2007; Harrington *et al.*, 1999).

The generality of the phenological mismatch problem is confirmed by the review of phenological shifts reported by Thackeray *et al.* (2010). In their analysis, the phenological shifts varied significantly among the different trophic levels: secondary consumers advanced less strongly than primary producers and primary consumers (Figure 3). This difference was found in marine, freshwater, and terrestrial ecosystems, indicating that phenological mismatches are likely in all ecosystems.

It is somewhat surprising that not all species within a food chain shift their phenology at the same rate, as there has been extensive selection on predators to keep their phenology matched to that of their prey under the natural range of annual temperature variation. This variation is normally larger than the increase in temperature due to climate change.

Figure 3 Phenological shifts from 1976 to 2005 for UK primary producers (red), primary consumers (orange), and secondary consumers (green). Negative values indicate a shift toward earlier phenology over time (reproduced from Thackeray SJ, Sparks TH, Frederiksen M, *et al.* (2010) Trophic level asynchrony in rates of phenological change for marine, freshwater and terrestrial environments. *Global Change Biology* 16: 3304–3313, with permission from Wiley).

Although there may not be a single answer for all species, two elements are of importance. First, “decisions” on the timing of life-history stages often have to be made weeks before any chance of a phenological match with the food. For instance, small passerine birds have to lay their eggs approximately a month before the time that they need ample food for provisioning their chicks, the time when they need to be matched to the phenology of their food. Similarly, migratory species often have to set their departure time from the wintering areas weeks before they have to match their reproductive phenology with favorable conditions. Animals thus have developed mechanisms that use predictive cues to time their reproduction or migration. The second element is that climate change has not led to a uniform increase in temperatures over the entire year. This lack of uniformity may thus lead to situations in which temperature increases less at the time of decision making, thus only marginally affecting the cues that are used, but in which temperature increases much more at the time of selection, thus affecting the phenology of the food (Visser *et al.*, 2004). Under these conditions, the cues are no longer accurately predicting the favorable period. One potential explanation why secondary consumers, in particular, are advancing their phenology too little is that these are often vertebrates that use photoperiod as one of the main cues in their timing (Bradshaw and Holzapfel, 2008), and photoperiod is obviously not changing due to climate change.

Studies on potential phenological mismatch have been carried out mostly on birds. Visser *et al.* (2011) evaluated 16 species interactions for which data on the shift in phenology of both the bird species and its prey species are known and found that in seven of these, climate change leads to a phenological mismatch. This review was, however, strongly biased to small forest insectivores (13 out of 16 studies), such as the great tit. Phenological mismatches do not always develop between the phenologies of breeding and food abundance. The American robin (*Turdus migratorius*), an altitudinal migrant, has advanced its arrival date at its breeding grounds 14 days over a 26-year period (1974–1999), although the date of snow melt has not changed, and as a consequence the delay between arrival and the date of bare ground is now 18 days (Inouye *et al.*, 2000). A second example comes from black-tailed godwits (*Limosa limosa*), which have not advanced their breeding phenology, but at the time the chicks hatch, the grass is taller and denser than 25 years ago, making it difficult for the nidifugous chicks to forage (Kleijn *et al.*, 2010).

There are just a few mammal studies on trophic mismatches. Yellow-bellied marmots (*M. flaviventris*) now come out of hibernation 3 weeks earlier, whereas the flowering time of their food plants has not changed, thus altering the relative phenology of the marmots and their food plants (Inouye *et al.*, 2000). Caribou (*R. tarandus*) in Greenland need to time the birth of their calves with the plant-growing season in order for their calves to have sufficient suitable food. Calving date advanced just 3.8 days between 1993 and 2006 (2.7 days per decade), whereas the phenology of onset of the plant-growing season advanced by 4.6 days (3.3 days per decade). Thus, caribou are getting increasingly mismatched (Post and Forchhammer, 2008).

Among amphibians, breeding phenology has shifted in some species, but not in all (Beebe, 1995), and this has

affected the trophic interactions between prey and predators. In the UK, newts (*Triturus* spp.) now enter ponds earlier, whereas frogs (*Rana temporaria*) did not advance their breeding phenology. As a consequence, the larvae of the frogs are exposed to higher levels of newt predation.

For insects, the phenological match between the leaf-feeding moths or aphids and the bud opening of their host plants, or of flower- and seed-eating weevils and the flowering or seed setting of their host plant, has major fitness consequences (van Asch and Visser, 2007). As the phenology of insects and plants are affected by temperatures of different periods of spring, and because climate change leads to differential warming during these different periods, there is ample opportunity for mismatching to occur. This has been shown for the winter moth (*O. brumata*), for which the egg hatching date has advanced more in the past 25 years than the bud burst date of the oak (*Quercus robur*) (Visser and Holleman, 2001).

Mismatches among Life-History Stages

Phenological events need to be matched not only across species in a food chain but also with abiotic conditions, within trophic levels or even within-individual life histories (Miller-Rushing *et al.*, 2010). Examples of such within-individual mismatches are migrant species that first need to arrive at the breeding ground before they can start breeding. Similarly, the phenology of different life-history stages such as breeding and molt (fur in mammals or feathers in birds) need to be phenologically matched. Not many studies have addressed this explicitly, but as some life-history stages are affected by temperature whereas others are not, climate change could potentially disrupt the phenological matches within individuals’ life cycles (Crozier *et al.*, 2008; Miller-Rushing *et al.*, 2010).

The best known examples of differential shifts in the phenologies of coupled life-history traits are arrival date and breeding date in migratory birds, where a lack of the shift in arrival date could potentially constrain shifts in breeding phenology (Both and Visser, 2001). Another example comes from a study on red deer (*Cervus elaphus*) (Moyes *et al.*, 2011), in which the phenologies of six traits were measured over a 28-year period. In female deer, parturition dates advanced by 11.8 days (4.2 days per decade), whereas the date of first oestrus advanced by only 7.3 days (2.6 days per decade). In male deer, the phenologies of antler casting and cleaning advanced by 5.6 (2.0 days per decade) and 7.3 days (2.6 days per decade), respectively. Interestingly, the end of the rut shifted twice as fast as its start dates: 12.0 versus 5.9 days (4.3 vs. 2.1 days per decade), respectively. It is likely that the phenologies of these traits are differentially affected by temperature or by different temperature periods, leading to a potential mismatch in the phenology of the deer’s life-cycle stages.

Consequences of Shifts in Phenology

Consequences for Population Viability

Climate change leads to major shifts in phenology, and in many cases these shifts do not seem to be of the appropriate

magnitude, leading to a phenological mismatch (Visser and Both, 2005). As there is ample evidence that mismatched reproduction has consequences for reproductive success and survival (Thomas *et al.*, 2001), it is likely that climate change will affect population viabilities by inducing these non-adaptive shifts in phenology (Miller-Rushing *et al.*, 2010). There are, however, only a few studies that have addressed the consequences of phenological shifts on population processes.

In a study on 100 European migratory bird species, Møller *et al.* (2008) found that the species that declined the most in breeding numbers over the period 1990–2000 were those that advanced their migration phenology the least (Figure 4). Although it is not clear how the lack of a shift in phenology affects population numbers, this multispecies analysis does indicate that there is a link between shifts in phenology and population viability.

A number of single-species studies confirm a link between shifts in phenology and population numbers. In a study on a number of pied flycatcher (*F. hypoleuca*) populations in the Netherlands, Both *et al.* (2006) found a significant relationship between the phenology of the food peak and the population trend in the flycatchers: populations declined the most in the areas with the largest phenological mismatch. In another analysis, population trends of six long-distance migrant species between 1984 and 2004 were compared in forests, where there is a sharp invertebrate food peak, and marshes, where the food peak is much less pronounced. As predicted, the populations in forests declined (by 38%), whereas those of the same species in marshes did not systematically decline (Both *et al.*, 2010).

The reproductive phenology of caribou (*R. tarandus*) in Greenland is under control of photoperiod, whereas the

phenology of plant growth is affected by spring temperatures. As temperatures have increased, there is now a phenological mismatch between the timing of calving by caribou and the timing of plant growth (Post and Forchhammer, 2008). This has had consequences for reproduction: offspring mortality increased and offspring production has dropped fourfold. Another study on mammals, however, did not show clear population effects of phenological mismatches. In Soay sheep (*Ovis aries*), there was no effect of the phenological mismatch on offspring survival, although this was not unexpected as their environment is only weakly seasonal with vegetation being available all year round (Durant *et al.*, 2005). Another study, on red deer (*C. elaphus*), which does show shifts in phenology of various life-history traits but does not report whether or not animals get mismatched, found no changes over time in offspring birth weight or offspring winter survival (Moyes *et al.*, 2011).

It is clear that more studies are needed that link shifts in phenology to population viability. Given the frequent occurrence of phenological mismatches, it is likely that there will be consequences for population viability, with potential knock-on effects for biodiversity in general, but at present it is not possible to quantify these effects.

Consequences for Microevolution

Shifts in phenology due to climate change can be caused by phenotypic plasticity, in which individuals change their timing in response to temperature (see Conceptual Framework for Shifts in Phenology), or it can be due to genetic changes in the population in response to selection (microevolution). By far, phenotypic plasticity is the most common mechanism underlying phenological shifts. Gienapp *et al.* (2008) reviewed the evidence for genetic responses in long-term studies of vertebrates and found that there was very little evidence for genetic responses. One of the best known examples of genetic adaptation comes from an insect, the pitcher plant mosquito (*Wyeomyia smithii*) in which the phenology of entering diapause has changed genetically in response to a longer growing season. The mosquitoes now enter winter diapause at a shorter day length than 24 years ago (Bradshaw and Holzapfel, 2001).

Although the majority of phenological shifts are due to phenotypic plasticity, this does not mean that this plasticity is sufficient to keep species matched to their abiotic and biotic environments. Often the phenology of species responds either too strongly or too weakly to climate change, resulting in a phenological mismatch, indicating that plasticity is no longer adaptive. An example comes from great tits (*P. major*) in the Netherlands, where the timing of reproduction is phenotypically plastic but still the shift in phenology was insufficient to keep the breeding matched with the phenology of their food. As a result, there is now selection on the plasticity: The birds should respond more strongly to temperature, as is clear from the directional selection for the degree of plasticity (Nussey *et al.*, 2005). Interestingly, in a great tit population in the UK, plasticity is still adaptive and the breeding phenology changes at a similar rate as the phenology of the food (Charmantier *et al.*, 2008).

Figure 4 Population trends of European migratory bird species (1990–2000) in relation to shifts in spring migration phenology (days per year; 1960–2006). Negative values in the population trend indicate a decline in numbers, positive values an increase. Negative values in the shift in phenology indicate a shift toward earlier phenology over time (reproduced with permission from Møller AP, Rubolini D, and Lehikoinen E (2008) Populations of migratory bird species that did not show a phenological response to climate change are declining. *Proceedings of the National Academy of Sciences of the United States of America* 105: 16195–16200).

Although in the great tits a response to this selection on the degree of plasticity is estimated to be slow, in another example, on winter moth egg hatching date, plasticity is estimated to genetically shift rather rapidly (van Asch *et al.*, 2007). In this system, egg hatching date is too early, as the winter moths respond too strongly to temperature in their phenology compared to the phenology of bud burst of the oaks that the caterpillars feed on. However, based on the heritability of and the selection on egg hatching date, a quantitative genetic model predicts rapid adaptation in the degree of plasticity, which will restore the phenological match.

The key issue is thus at what rate species can change genetically. It is this rate of microevolution that will determine whether or not species will be able to adapt fast enough to prevent a decline in population viability and thereby a loss of biodiversity (Visser, 2008) as shifts in phenology due to phenotypic plasticity alone will not be sufficient because this plasticity will no longer be adaptive (*see* Consequences of Microevolution). Adaptation via immigration of individuals with genotypes adapted to warmer environments will also require microevolution as these genotypes will be better adapted to current temperature, but not, for instance, to the photoperiod of their new environment.

Outlook

There is ample evidence for phenological shifts due to contemporary climate change (*see* Observed Phenological Shifts Under Climate Change), but the data available are strongly skewed to plants and birds. Mammal, fish, amphibian, reptile, and invertebrate studies are quite rare, with the exception of studies on butterflies. One clear reason for this pattern is that birds and butterflies receive ample interest from the general public and can be easily observed, and as a consequence, long-term datasets based on monitoring programs in which the data are collected by amateurs are available for analysis. Also, data from aquatic and marine systems are less common than data from terrestrial systems. However, from the data that are available, it seems that the patterns found in these well-known groups are not fundamentally different from the less-studied groups or habitats (Figure 2). A possible exception is the degree to which climate change induces genetic changes, which seems to be higher in vertebrates.

There is also ample evidence that the observed shifts in phenology over the past decades are indeed due to climate change (*see* Linking Observed Shifts in Phenology to Climate Change). There are, however, important methodological problems with linking phenology to temperatures (Gienapp *et al.*, 2005). Often phenological events are simply correlated with the mean temperature or the sum of temperatures over a fixed period. This period is often a single month or a combination of months. One problem is that the correlation found depends on the choice of this period. The period yielding the best correlation can be established using a sliding-window approach to test all possible periods between two dates. But even within species, this best correlating period may differ among populations (Husby *et al.*, 2010). A second problem is that often the earliest individuals in a population already expressed their phenological trait before the end of the

period over which temperature is being averaged, and thus their phenology correlates with temperatures occurring after they expressed their trait. A final problem is that this fixed-period approach does not allow tests for an interaction with, for instance, photoperiod, which is an important cue in the phenology of many species.

These problems with a sliding-window approach can be avoided by analyzing phenology using proportional hazard models (Gienapp *et al.*, 2005). These models calculate the probability that the phenological event will occur every day under the assumption that it has not yet occurred. The model thus calculates how, for instance, temperature affects this probability, not only using the temperature of that day, but also integrating the temperatures of previous days. The weight of these previous days decreases with each passing day. Gienapp *et al.* (2005) assumed that this decrease follows a specific rule, whereas this assumption was relaxed in a model that combines a memory function of past temperatures with a sliding-window approach (van de Pol and Cockburn, 2011). Although these two methods have clear advantages over the classical sliding-window approach, they are not widely used, probably because of the ease with which the sliding-window model can be calculated and interpreted.

An approach fundamentally different from these statistical correlations that can be used to assess the effects of temperature on phenology comes from (neuro)physiological studies. Such studies will ultimately determine which environmental variables affect the phenology of a trait via the mechanisms underlying plasticity (Visser *et al.*, 2010). Obviously, this approach will not be possible for a large set of species, but by choosing the few species where research is feasible based on their differences in life-history traits (long- vs. short-lived, etc.), it may be possible to obtain general insights into whether temperature plays a direct role in the timing of life cycle events or, instead, whether this effect comes about indirectly, for instance, via the phenology of the vegetation (Schaper *et al.*, 2011).

The observed shifts in phenology are mainly due to phenotypic plasticity, as there is very little evidence for genetic changes (*see* Consequences of Shifts in Phenology). As discussed earlier, this plasticity is often no longer optimal, leading to phenological mismatches. If temperatures keep on increasing due to climate change, such suboptimal or maladaptive shifts in phenology will become more common and will have more severe consequences, both for individuals (Visser *et al.*, 2004) and for populations (Reed *et al.*, 2010). This is simply because organisms have evolved under a certain set of correlated abiotic variables and it would be very unlikely that any response to these abiotic variables would still be optimal when climate change leads to a set of abiotic variables that are correlated differently (Visser *et al.*, 2004). Moreover, there may be nonlinear effects or constraints in plasticity that will prevent any further advancement of phenology at higher temperatures. At what temperatures this may become important can be predicted only by in-depth causal studies on the relationship between phenology and temperature (*see* Outlook).

There is already some evidence that shifts in phenology have consequences for population viability and from there for biodiversity (*see* Consequences of Shifts in Phenology).

Clearly, more studies are needed to assess how large this impact may be. But the next challenge will be to forecast the impact of future climate change on biodiversity. This is particularly important because future climate change is not determined but will depend on the greenhouse gas emission targets that are set to reduce global climate change. It is of crucial importance that ecological consequences of socioeconomic development are included while setting these climate targets (Visser, 2008). Phenology will play an important role in the models that assess climate change impact because of the large fitness consequences of phenology. Ultimately, models that combine evolution and ecological processes (e.g., Reed *et al.*, 2011) have to be developed (Jenouvrier and Visser, 2011), and from these the consequences of climate change, via shifts in phenology, of the different climate scenarios (IPCC, 2007) on biodiversity have to be estimated.

Glossary

ATP synthetase Membrane-associated protein complex that couples exergonic fluxes of H^+ across the membrane to ADP phosphorylation, or vice versa.

Carboxylase Enzyme that catalyzes the formation of a C—C bond between inorganic C (CO_2 or HCO_3^-) and some organic molecule.

Chemiosmotic energy coupling Exergonic (photo)-chemical redox reaction, or an exergonic hydrolysis of a phosphate anhydride or thioester, coupled to endergonic ion (normally H^+) transfer across a membrane, or vice versa.

Chromophore Organic molecule that absorbs photosynthetically active radiation and either carries out photochemistry or transfers excitation energy to another chromophore that carries out photochemistry. Always bound to a polypeptide in the photosynthetic apparatus.

Reaction center (Bacterio)chlorophyll–protein complex that performs the primary photochemical reactions of photosynthesis, the earliest products being the oxidized reaction center (bacterio) chlorophyll at the outside/thylakoid lumen side and a reduced (bacterio) chlorophyll (RC1) or reduced (bacterio) phaeophytin (RC2) on the cytosol/stroma side of the photosynthetic membrane.

Photosynthesis, or building with light, involves the use of electromagnetic energy to bring about endergonic reactions. The concept is generally extended to the use of the more immediate photochemical products to reduce CO_2 and (in most photosynthetic organisms) oxidize H_2O and evolve O_2 , this extended definition is used here. This article deals with the partial processes of photosynthesis in the order in which they occur subsequent to initial photon absorption. Starting with the characteristics of the photon-harvesting apparatus, we then consider the photochemical reaction centers and their immediate products, which are an oxidant and a reductant oxidation–reduction and/or an ion (H^+ or, rarely, Cl^-) gradient. These light-harvesting and photochemical reactions are invariably associated with membranes. Next in temporal sequences are the reactions that lead to the phosphorylation of ADP and generation of strong (NAD(P)H) reductant; these reactions are also membrane related. Finally, we deal with the use of ATP and NADPH in CO_2 fixation and other endergonic reactions; these reactions are either in aqueous solution or associated with membranes other than those in which primary photochemistry occurs. In O_2 -evolving organisms, the basic photosynthetic equation is (1)

Light Harvesting and Excitation Energy Transfer to Reaction Centers

For photochemical reactions to occur, photons must be absorbed by a pigment. In the majority of photosynthetic organisms, only one in 100 to one in 1000 pigment molecules can actually bring about useful (to the organisms) photochemical reactions. The photochemically inactive antenna

pigments serve to absorb radiation and transfer the energy as excitation energy (i.e., not in stable chemical forms) to photochemically active pigments in reaction centers. This division of labor presumably relates to the generally rather “dilute” nature of solar radiation, such that each pigment molecule absorbs a photon on the order of a few times each second, yet the photochemical machinery and the immediate downstream reactions can react hundreds or thousands of times per second. Accordingly, the resource-expensive (energy, nitrogen, iron) reaction centers and the related catalytic machinery that is energetically and temporally downstream of the reaction centers are present as a small number of copies of the catalysts relative to the number of molecules of light-harvesting pigment; this arrangement is presumably related to optimal allocation of resources in natural selection.

A very small number of species, all of them members of the Archaea, do not accord with this generalization about antenna pigments and reaction centers. These Halobacteria use carotene pigments associated with membrane-spanning proteins to catalyze their primary photochemical reaction, with each protein molecule associated with its pigment molecule acting as a light-energized H^+ (bacteriorhodopsin) or Cl^- (halorhodopsin) pump (see Reaction Centers and Primary Photochemistry).

By contrast, all other photosynthetic organisms are (eu)Bacteria and their symbiotic eukaryotic descendants that use the antenna plus reaction center system. In all of these organisms the pigment involved in the primary photochemical reactions is a Mg- (very rarely Zn-) binding cyclic tetrapyrrol, chlorophyll (in O_2 -evolvers) and bacteriochlorophyll (in non- O_2 -evolvers). Chlorophylls always occur in a functional photosynthetic apparatus in association with proteins in, or more rarely on, bilayer membranes. In all chlorophyll-containing organisms there are some chlorophyll molecules that act as antenna pigments. In many such organisms (e.g., all green algae and higher plants) the great

Table 1 Chemistry, taxonomy, and location of light-harvesting pigment–protein complexes

<i>Chromophores</i>	<i>Taxonomy</i>	<i>Location</i>
O₂-Evolvers		
Chlorophylls <i>a</i> and <i>b</i>	Chlorophyta, Euglenophyta, Chlorarachniophyta, Embryophyta; “chloroxybacterial” cyanobacteria	Integral membrane protein of thylakoid
Chlorophylls <i>a</i> + (usually) <i>c</i>	Cryptophyta, Heterokontophyta (Bacillariophyceae, Chrysophyceae, Phaeophyceae, Tribophyceae), Haptophyta, Dinophyta	Integral membrane protein of thylakoid
Chlorophyll <i>a</i> , peridinin	Dinophyta	Peripheral protein on stromal surface of thylakoid
Phycobilinogen	Cyanobacteria <i>sensu stricto</i> , Rhodophyta	Phycobilisomes on stromal/cytosol surface of thylakoid
	Cryptophyta	Thylakoid lumen
Non-O₂-Evolvers		
Bacteriochlorophylls <i>a</i> and <i>b</i>	Proteobacteria: purple sulfur bacteria (Chromatiaceae), purple nonsulfur bacteria (Rhodospirillaceae)	Integral membrane protein of “chromatophores”
Bacteriochlorophyll <i>g</i>	Heliobacteriaceae	Integral membrane protein of plasmalemma
Bacteriochlorophylls <i>c</i> , <i>d</i> , and <i>e</i>	Chlorobiaceae, Chloroflexaceae	Chlorosomes on the cytosol side of plasmalemma

majority of light harvesting is carried out by chlorophyll–protein complexes, in this case with chlorophylls *a* and *b* as the major light-absorbers with minor contributions from carotenoids. In the case of algae with chlorophyll *a* and, usually, chlorophyll *c*, carotenoids generally have a more significant role in light harvesting by pigment–protein complexes. In a final group of organisms (mainly cyanobacteria and red algae), the light-harvesting pigments in addition to chlorophylls are open-chain tetrapyrrol pigments covalently bound to proteins, attached to the outer (stromal in red algae, cytosolic in cyanobacteria) side of the photosynthetic membranes, or in the thylakoid lumen of cryptophyte algae. The variations in the chemistry and location of light-harvesting pigment–protein complexes are indicated in **Table 1**.

A number of energetic and structural constraints determine the spatial relationship of the different pigments in light-harvesting complexes. The energetic constraint is that energetically efficient excitation energy transfer among antenna pigments, and from antenna pigments to reaction centers, involves an unavoidable energy loss during the transfer. Thus, the peripheral pigments in the antenna have a higher energy content of their excited states than do the inner antenna pigments, and those in turn have a more energetic excited state than the reaction center pigment. The situation is complicated by the occurrence of two readily accessible excited states in some photosynthetic pigments, and especially in the chlorophylls. Here the second excited state, produced by absorption of blue radiation, has a higher energy content than the first excited state, corresponding to the *in vivo* absorption in the red (chlorophylls) or infrared (bacteriochlorophylls) region of the electromagnetic spectrum. It is the first excited state that performs the primary photochemistry in (bacterio) chlorophyll-based photosynthesis. Thus, photons that excite (bacterio) chlorophylls to the second excited state are not directly used in photochemistry via this state, but only after they become converted to the first excited state; this also applies to excitation energy transfer among pigments.

These energetic requirements are reflected in the structure of the light-harvesting apparatus. Thus, the pigments are

arranged spatially such that those absorbing shorter-wave-length (thus higher energy) photons are generally at a greater distance from the reaction center, whereas those absorbing at longer wavelengths (more similar to that of the reaction center pigments) are close to the reaction center. Furthermore, the smaller-scale arrangement of individual chromophores in the pigment–protein complexes is also a function of the distance between chromophores over which effective excitation energy transfer can occur; these arrangements have been shown for a number of light-harvesting pigment–protein complexes using X-ray crystallographic techniques.

A related consideration is that of how many chromophore molecules can be involved in light harvesting for a given reaction center. A *minimum* estimate of the upper limit of this number comes from determining the ratio of pigment molecules serving a given kind of reaction center and dividing it by the number of the type of reaction center that they serve. This is clearly most readily determined when there is only one kind of reaction center in the organisms concerned, as is the case in organisms that do not evolve O₂, but it is also applicable to O₂-evolvers, which invariably have two kinds of reaction center (*see* Reaction Centers and Primary Photochemistry). Such computations suggest that up to 1000–2000 chromophores occur per reaction center of a given type. Even more pigment molecules can be involved in excitation energy transfer to a given reaction center if pigment molecules are not all dedicated to a given reaction center but can be involved in excitation energy transfer to several nearby centers.

Another size-related aspect of light harvesting occurs at all scales, but becomes most obvious at a larger scale: this concerns the optical thickness of the cell or tissue in which the photosynthetic apparatus occurs. A small optical thickness involves a smaller physical thickness for a given pigment concentration per unit volume, or a lower concentration of pigment per unit volume if there is a fixed physical thickness, or a combination of the two. A large optical thickness means more self-shading of pigment molecules, so that the average specific absorption coefficient of each pigment molecule is

lower. Furthermore, in a given radiation environment, it takes longer for a pigment molecule to absorb enough photons to cover the energy cost of its synthesis in a cell or organ with more self-shading. Finally, the cells or tissues with a small optical thickness, and hence smaller package effect, have a greater opportunity for the spectral diversity of pigments that they contain to be manifest in the specific wavelengths of radiation that are absorbed. The ultimate in large optical thickness is found in the thalli of some seaweeds that, with more than one millimole of pigment per square meter, look black to the human observer (because of low reflectance or transmittance, with minimal wavelength dependence of these two processes due to high absorbance at all visible wavelengths) regardless of whether their pigments are of the kind found in green, brown, or red algae.

A final aspect of light harvesting concerns the occurrence of pigment molecules in photosynthetic cells that (of necessity) absorb radiation but that show little or no transfer of excitation energy to reaction centers. Examples of such pigments are β -carotene, and at least some portion of the other carotenoids. The pigments serve as photoprotectants, quenching the triplet excitation states of chlorophyll and singlet oxygen in the case of β -carotene, and as nonphotochemical quenchers of excess (singlet) excitation energy of antenna pigments in the case of phototransformable carotenoids such as violoxanthin–antheroxanthin–zeaxanthin and diadinoxanthin–diatoxanthin in certain O_2 -evolvers.

Reaction Centers and Primary Photochemistry

We have seen (*in* Light Harvesting and Excitation Energy Transfer to Reaction Centers) that the halobacteria, with their halorhodopsin or bacteriorhodopsin pigments, do not have separate antenna and reaction center pigments. These organisms have active transport of ions (H^+ out of the cell or Cl^- into it) as the sole product of photochemistry external to the pigment–protein complex. The other photosynthetic organisms, with (bacterio)chlorophyll as their photochemically active pigment, do have reaction centers; these organisms are predominant in terms of number of species, habitats occupied, and quantity of energy and materials transformed.

In all of the (bacterio)chlorophyll-based reaction centers the primary photochemical event is the production of a reduced compound on the side of the membrane abutting the cytosol (prokaryotes) or chloroplast stroma (eukaryotes) and

an oxidized compound on the side of the membrane adjacent to the external medium (many prokaryotes) or thylakoid lumen (almost all O_2 -evolvers). The photochemical redox process thus involves the transfer of an electron from near one side of the membrane to near the other side of the membrane. Furthermore, the photochemically active pigment is bacteriochlorophyll *a*, *b*, or *g*, or chlorophyll *a* (or apparently, in one case, chlorophyll *d*), bound to protein (Table 2).

While all (bacterio)chlorophyll-based reaction centers share this basic mechanism, such centers can be divided into two types termed RC1 and RC2 (Table 2). In the RC1 type (e.g., the reaction centers of the Chlorobiaceae and Helio-bacteriaceae, and PSI of O_2 -evolving organisms), the (bacterio)chlorophyll catalyst of primary photochemistry that is oxidized generates an oxidant (oxidized (bacterio)chlorophyll) at a redox potential of $+0.25$ – $+0.45$ V, while the primary reductant is another form of (bacterio)chlorophyll with a redox potential of -0.6 – -0.7 V. In the RC2 type (e.g., the reaction centers of the Chloroflexaceae and Proteobacteria, and PSII of O_2 -evolvers), the oxidized (bacterio) chlorophyll product of primary photochemistry has a redox potential of $+0.45$ (bacteria that cannot evolve O_2) to $+0.1$ V (O_2 -evolving organisms), while the reductant (a (bacterio)pheophytin, i.e., a (bacterio)chlorophyll without Mg) has a redox potential of -0.8 V (bacteria that cannot evolve O_2) to -0.5 V (O_2 -evolvers).

The primary charge separation is relatively unstable, and reduction of a more stable compound with a higher redox potential, and which is less prone to back-react yielding chemiluminescence, occurs within ~ 100 ps. For RC1 this secondary acceptor is a phylloquinone (vitamin E) followed, within ~ 100 ns, by electron transfer to iron–sulfur centers. For RC2 the secondary acceptor is a ubi- (non- O_2 -evolvers) or plasto- (O_2 -evolvers) quinone bound to the reaction center; the resulting semiquinone free radical reduces a second, chemically identical quinone within ~ 300 μ s.

The reduction of the primary oxidized product of photosynthesis takes longer than does oxidation of the primary reduced product. For RC1, and for the RC2 of organisms that do not evolve O_2 , the compound that reduces the primary oxidant is a c-type cytochrome or (in many O_2 -evolvers) the cuproprotein plastocyanin; this reduction takes ~ 200 μ s. For RC2 in O_2 -evolvers (i.e., PSII) the reductant of the primary oxidant is a tyrosine residue termed Y_Z in a polypeptide (D1), which, with polypeptide D_2 , binds the reaction center chlorophyll *a*. The action takes ~ 200 ns, and the oxidized

Table 2 Reaction centers of various photosynthetic organisms that contain (bacterio)chlorophyll

Type of reaction center	Chromophore involved in primary photochemistry	Taxonomy
O_2 -Evolvers		
RC1 (as PSI)	Chlorophyll <i>a</i> (P700)	All O_2 -evolvers
RC2 (as PSII)	Chlorophyll <i>a</i> (P680)	All O_2 -evolvers
Non- O_2 -Evolvers		
RC1	Bacteriochlorophyll <i>g</i> (P798)	Helio-bacteriaceae
RC1	Bacteriochlorophyll <i>a</i> (P840)	Chlorobiaceae
RC2	Bacteriochlorophyll <i>a</i> (P840)	Chloroflexaceae
RC2	Bacteriochlorophyll <i>a</i> or <i>b</i> (P870 or P890)	Chromatiaceae and Rhodospirillaceae

tyrosine is re-reduced by a protein-bound cluster of four Mn in $\sim 200 \mu\text{s}$. All of the RC1 reaction centers have, as known from molecular genetic data, a common ancestry, whereas RC2 reaction centers also have a common ancestry that differs from that of RC1. Further discussion of evolutionary points are beyond the scope of this article.

Membrane-Associated Reactions Leading from Primary Photochemistry to ATP and NAD(P)H

Dealing first with RC1, a role that these reaction centers can perform in most, if not all, of the organisms in which they occur is cyclic electron transport. This process involves ubiquinone (non- O_2 -evolvers) or plastoquinone (O_2 -evolvers) and a cytochrome $b\text{-}c_1$ (non- O_2 -evolvers) or cytochrome $b_6\text{-}f$ (O_2 -evolvers) complex. The link between the iron-sulfur reductant of RC1 and the quinone involves the soluble FeS protein ferredoxin (less commonly the Fe-free flavodoxin), and other redox catalysts that are incompletely characterized and that are probably variable among or even within taxa. One of these could be NAD(P)H dehydrogenase. The oxidizing end is much better understood, with the cytochrome $b\text{-}c_1$ ($b_6\text{-}f$) complex reducing a cytochrome c (or plastocyanin) and hence the primary oxidant of the photochemical reaction.

The bioenergetic role of cyclic electron transport is the pumping of H^+ from the cytosol (or stroma) to the external environment (or thylakoid lumen) compartments. Two H^+ per electron are pumped via the quinone and the cytochrome complex. If the NAD(P)H dehydrogenase is involved, then a further 2H^+ per electron could be transferred. A major role for these pumped H^+ is to move back across the membrane through the ATP synthetase; 4H^+ energize the phosphorylation of one ADP. If all the absorbed photons are used to energize RC1, each photon could produce $0.5\text{--}1.0$ ATP, depending on the involvement of NAD(P)H dehydrogenase. An alternative use of the H^+ gradient is to energize secondary active transport coupled to exergonic H^+ fluxes.

Another role for RC1, and apparently the major one in almost every situation in which RC1 occurs, is to generate a reductant at a low enough redox potential to reduce CO_2 to carbohydrate. As will be seen (*in Use of NAD(P)H and ATP in CO_2 Fixation and Other Reactions*), in many cases the reductive step in CO_2 fixation involves an energetic input from ATP, and here the reductant is NAD(P)H. The path from the reduced protein-bound iron-sulfur involves ferredoxin and a membrane-bound ferredoxin-NAD(P)H reductase. The reduction of ferredoxin and NAD(P)H, and hence the reduction of CO_2 (or NO_2^- , or other electron acceptors), requires an input of (weaker) reductant at the oxidizing end of the photosystem. For members of the Chlorobiaceae and Helio-bacteriaceae, the reductant is ultimately some exogenous organic or inorganic electron donor (other than H_2O) such as S^{2-} , which supplies electrons to the oxidizing end of the photosystem via cytochrome c , with or without the involvement of the cytochrome $b\text{-}c_1$ complex. For the O_2 -evolvers, PSI (photoreaction I) is supplied with reductant by PSII (photoreaction II) via plastoquinone, the cytochrome $b_6\text{-}f$ complex, and cytochrome c_6 or plastocyanin.

RC2 does not produce a stable reductant with a redox potential that is sufficiently negative to reduce ferredoxin or NAD(P)H^+ . For the photosynthetic Proteobacteria and the Chloroflexaceae, a major function of the RC2 reaction center is in a cyclic electron transport pathway. This uses the ubiquinol produced at the reducing end of the reaction center to reduce the cytochrome $b\text{-}c_1$ complex, and then cytochrome c , and finally the oxidant produced by the reaction center is reduced. This mechanism pumps 2H^+ per electron, and hence per photon, whose excitation energy is transferred to the reaction center. One use of the H^+ gradient is, as for cyclic electron flow and H^+ pumping by RC1, to generate ATP. Another is to use a weak reductant (e.g., S^{2-}) to generate a strong reductant (NADH). Here electrons are transported against an energy difference using the energy from the flux of H^+ from the medium back to the cytosol. This process is the reverse of the active H^+ transport caused by the respiratory, exergonic, electron transport from NADH to S^0 (generating S^{2-}). Similar uses of the H^+ gradient can be envisaged in the Halobacteriaceae.

The other, and quantitatively predominant, occurrence of RC2 in the biosphere is as PSII of O_2 -evolvers. Here the usual immediate sink for the electrons from reduced plastoquinone (= plastoquinol) is the cytochrome $b_6\text{-}f$ complex, with subsequent sequential reduction of cytochrome c_6 or plastocyanin, PSI, ferredoxin, and NADP^+ , or, finally to a smaller extent, some other oxidant such as NO_2^- or O_2 (see the following). The corresponding electron donor to the oxidizing side of PSII, after the polypeptide-bound tyrosine Y_Z and polypeptide-bound Mn, is the very weak reductant H_2O . It appears that PSII does not engage in cyclic electron transport involving the cytochrome $b_6\text{-}f$ complex in the manner of RC2 in the Proteobacteria and Chloroflexaceae, although it may perform cyclic electron transport via cytochrome b_{559} , a redox catalyst with no analog in the RC2 of non- O_2 -evolvers. This cyclic electron transport probably occurs as a photochemical means of dissipating excess, and potentially damaging, excitation of PSII.

Putting PSII and PSI together, in terms of photon requirement, the transport of one electron from H_2O to NADP^+ , and hence CO_2 , and the associated H^+ transport, requires the energy of two photons, one used by PSII and the other by PSI. The stoichiometry of H^+ transport is that one H^+ is left in the thylakoid lumen, and one H^+ is taken up in the cytosol or stroma, per electron moved from H_2O to NADP^+ and then to CO_2 . In addition, for each electron moving through plastoquinone and the cytochrome $b_6\text{-}f$ complex, two H^+ are transferred from the cytosol or stroma to the thylakoid lumen. Thus, per electron moved from H_2O to NADP^+ (and thence CO_2), 3H^+ are moved from the cytosol or stroma to the thylakoid lumen:

where the subscript (s) means stroma (or cytosol of cyanobacteria) and the subscript (t) means thylakoid lumen.

With an H^+/ATP of 4 in ATP synthetase, the ADP phosphorylation corresponding to the recycling of 12H^+ can be

described by

Thus, each electron moved from H_2O to NADP^+ generates 0.75 ATP, so that 3ADP are phosphorylated per 2NADP^+ (and hence 1CO_2) reduced. This can be seen when Eqs. (2) and (3) are added together to yield

This has important implications for the minimum photon cost of CO_2 fixation in O_2 -evolvers, which is 8 photons absorbed per CO_2 reduced to carbohydrate.

In addition to the reduction of CO_2 and NO_2^- by PSI, there is also the reduction of O_2 to form, ultimately, H_2O . The Mehler Peroxidase reaction involves two electrons from the reducing end of PSI passing to two O_2 to form two superoxide anions, which are then dismutated by the enzyme superoxide dismutase to form one H_2O_2 and one O_2 . The H_2O_2 , plus ascorbate, are then acted on by the enzyme ascorbate peroxidase, which converts one H_2O_2 and one ascorbate to two H_2O and one dehydroascorbate, involving (via other enzymes) two more electrons from PSI to regenerate the ascorbate co-substrate from dehydroascorbate. Overall, the reaction involves the evolution of one O_2 at the oxidizing end of PSII and the uptake of one O_2 at the reducing end of PSI, so that there is no net evolution or uptake of O_2 . The reaction can be quantified by the use of $^{18}\text{O}_2$ tracer. The Mehler Peroxidase reaction is a means of disposing of active, and potentially damaging, oxygen species produced in thylakoid redox reactions and, to the extent that superoxide production by PSI can be increased above the unavoidable basal rate, a means of photochemical energy dissipation and of ATP generation not paralleled by NADP^+ reduction as an alternative to cyclic photophosphorylation.

The photon cost of CO_2 fixation in terms of incident irradiance depends on the photon cost of CO_2 fixation in terms of absorbed photons (8 in the case mentioned here) and the fraction of the incident photons that are absorbed (*see* Light Harvesting and Excitation Energy Transfer to Reaction Centers). The catalytic capacity of the reactions generating NAD(P)H and ATP can, under many circumstances, constrain the rate of CO_2 fixation when photon supply is not limiting. However, in some cases it is the supply of CO_2 , or the capacity of CO_2 -assimilation reactions (*see* Use of NAD(P)H and ATP in CO_2 Fixation and Other Reactions), that constrains the CO_2 fixation rate at saturating light supply. The capacity for light harvesting relative to that for primary photochemical reactions and downstream thylakoid reactions and CO_2 fixation reactions (*see* Use of NAD(P)H and ATP in CO_2 Fixation and Other Reactions) depends on the irradiance that the plant has encountered in its evolutionary history (genetic adaptation) and during the life of an individual (phenotypic acclimation). In both adaptation and acclimation, the response to low light is an increased capacity for light harvesting relative to downstream reactions, and vice versa for the response to high light.

In O_2 -evolvers the rate and (incident) photon cost of CO_2 fixation at limiting incident irradiances, and the rate of CO_2 fixation at saturating irradiances, can be reduced by photoinhibition. This phenomenon has its basis in damage to the PSII reaction center by one in 10^6 to 10^7 of the photons whose excitation energy reaches the reaction center. In the absence of any protective mechanisms, this photodamage would occur more rapidly at higher incident photon flux densities, but would result in a greater fractional inhibition of photosynthesis when measurements on organisms exposed to high incident photon flux densities are subsequently made at lower (rate-limiting) irradiances. The observed phenomenon of photoinhibition, that is, a reduced rate of photosynthetic CO_2 fixation during, and following, exposure to (especially high) irradiances, is not solely a function of photodamage occurring faster than it can be repaired. Thus, the decreased photosynthetic rate can be a result of diversion of the products of PSII photochemistry to processes other than CO_2 fixation at high incident irradiances, for example, to cyclic electron flow round PSII or to the Mehler Peroxidase reaction, decreasing the photochemical unusable "excess" excitation of PSII. More commonly, excitation energy is prevented from reaching the PSII reaction center by dissociation of some of the light-harvesting pigment-protein complexes (Table 2) from the reaction center, or by nonphotochemical quenching of excitation in the light-harvesting complexes by processes triggered by very low pH in the thylakoid lumen. This increased acidification of the lumen is a result of photochemically driven H^+ pumping in excess of the rate at which H^+ is recycled through the ATP synthetase due to restricted ATP consumption and hence limited ADP availability, and can dissipate excitation energy via a xanthophyll cycle mechanism in all but cyanobacteria and red algae and, in all O_2 -evolvers, via mechanisms not related to a xanthophyll cycle.

Use of NAD(P)H and ATP in CO_2 Fixation and Other Reactions

Most of the ATP and NAD(P)H generated in the thylakoid reactions in O_2 -evolvers is used in CO_2 reduction to (CH_2O) . Other uses for the ATP resulting from photochemical reactions include photoassimilation of exogenous organic compounds, as well as other transport and biochemical reactions. Photochemically produced reductant can be used for reductive biosyntheses, such as reduction of NO_3^- , NO_2^- and SO_4^{2-} . These uses of ATP and reductant notwithstanding, the major global biogeochemical role of NAD(P)H and ATP generated in photochemical reactions is the conversion of CO_2 to carbohydrates; a net primary production of ~ 100 Pg carbon per year worldwide is carried out by O_2 -evolvers. However, some CO_2 is fixed by non- O_2 -evolving autotrophs. In the Chlorobiaceae, the reverse tricarboxylic acid cycle is used, whereas the Chloroflexaceae use the hydroxypropionate cycle (Table 3). These two processes each involve more than one carboxylation reaction in converting CO_2 to carbohydrates. By contrast, the photosynthetic carbon reduction cycle used in the Proteobacteriaceae and in all O_2 -evolvers involves but a single carboxylase, that is, ribulose-1,5-bisphosphate carboxylase-oxygenase (RUBISCO), in converting CO_2 to

Table 3 Taxonomic distribution and energy costs of CO₂ assimilation reactions in photosynthetic organisms

<i>CO₂ assimilation reaction</i>	<i>Taxonomy</i>	<i>NAD(P)H cost per net CO₂ fixed</i>	<i>ATP cost per net CO₂ fixed</i>
Reverse tricarboxylic acid cycle	Chlorobiaceae	2	?
Hydroxypropionate pathway	Chloroflexaceae	2	?
RUBISCO and photosynthetic carbon reduction pathway

(ii) In low CO ₂ –high O ₂ (present atmosphere or water in equilibrium with it)	Proteobacteriaceae (Chromatiaceae) Rhodospirillaceae	2	3
(a) Diffusive CO ₂ entry to RUBISCO, with photorespiratory carbon oxidation cycle	C ₃ land plants; some algae	2.8	4.2
(b) Active transport of inorganic C to RUBISCO by a process that does not involve C—C bond formation	Cyanobacteria; many algae	2	4–5
(c) Active transport of inorganic C to RUBISCO by a process that does involve C—C bond formation	C ₄ higher plants	2	5
	CAM higher plants	2	6.5

carbohydrates, although some essential biosyntheses involve parallel, quantitatively minor, carboxylation reactions catalyzed by other carboxylases.

RUBISCO, as its name suggests, not only catalyzes a carboxylase reaction but also has an oxygenase activity. The oxygenase activity is competitive with the carboxylase activity. Thus, the oxygenase is not a significant reaction in proteobacterial photosynthesis in their typical high-CO₂, low-O₂ habitats where heterotrophic organisms dominate and organic carbon sedimentation into the habitat exceeds O₂ diffusion into it. Furthermore, the oxygenase activity would not have been significant in the high-CO₂, low-O₂ world prior to 2 billion years ago, that is, for the first 1.5 billion years or so of the occurrence of RUBISCO. When oxygenase activity is negligible, the conversion of 1CO₂ to the carbohydrate redox level by the photosynthetic carbon reduction cycle needs 2NAD(P)H and 3ATP:

Equation (5), showing the consumption of NADPH and ATP in CO₂ fixation, can be combined with Eq. (4), describing the production of NADPH and ATP by light-driven processes in the thylakoid, to give the overall equation for photosynthesis (Eq. (1)).

While the reductant requirement per CO₂ assimilated is the same as for the reverse tricarboxylic acid cycle and the hydroxypropionate cycle, the ATP requirement is greater for the photosynthetic carbon reduction cycle (see Table 3).

The greater energy requirement for the photosynthetic carbon reduction cycle than for the other carbon fixation cycles is exacerbated in the present atmosphere, or in natural waters in equilibrium with it. If CO₂ enters by diffusion (C₃ physiology) then there is significant oxygenase activity of RUBISCO, although there is significant variability among RUBISCOs of different organisms in selectivity for CO₂ relative to O₂. The oxygenase activity produces phosphoglycolate, and thence glycolate. Recycling this glycolate to carbohydrate has a significant energy cost; the excretion of glycolate in

aquatic organisms imposes an even greater energy cost for net CO₂ fixation. The energy cost of the net fixation of 1CO₂ from the present atmosphere by a vascular land plant with C₃ physiology (CO₂ reaching RUBISCO by diffusion) is some 2.8 NADPH and 4.2 ATP. This contrasts with the 2NADPH and 3ATP required when CO₂ is saturating and, regardless of O₂ concentration, there is no oxygenase activity (see Table 3).

C₃ physiology occurs in the great majority of species of terrestrial embryophytes, a few lichens and asymbiotic terrestrial algae, and some aquatic algae and embryophytes. Some red algal RUBISCOs have the highest reported selectivity for CO₂ over O₂, so that glycolate production may be minimal in red algae with C₃ physiology. The algae, lichens, and bryophyte gametophytes with C₃ physiology have limitations on photosynthesis by CO₂ diffusion that vary with the structure of the photosynthetic apparatus, whether the medium supplying inorganic carbon (CO₂ + HCO₃[−]) is air or water, the CO₂ concentration in the medium, and the thickness of the diffusion boundary around the photosynthetic structure. In sporophytes of embryophytes in water the situation is as for gametophytes, whereas for sporophytes in air there is the additional complication of stomata. These variable conductance apertures connecting intercellular gas spaces to the atmosphere are crucial in maintaining land plants in a hydrated state when soil water availability is low and/or the atmosphere is very dry, and permit CO₂ fixation in the light when the plants can remain hydrated with open stomata. In most cases the C₃ vascular plant sporophytes on land fix CO₂ under conditions in which the rate of fixation is about one-third constrained by CO₂ diffusion and two-thirds constrained by biochemical reactions. In other words, were CO₂ diffusion constraints to be reduced by 10%, the rate of photosynthesis would increase by 3%; if the constraints from biochemistry were reduced by 10%, the rate of CO₂ fixation would increase by 7%. The fractional limitation of photosynthesis by CO₂ diffusion in aquatic plants with C₃ physiology is more variable than in the terrestrial vascular plant sporophytes with this photosynthetic physiology.

In a number of species of O₂-evolvers the supply of CO₂ from the environment to RUBISCO involves some energized

process that gives a higher CO_2 concentration, and CO_2/O_2 ratio, near RUBISCO than that in the medium. Such mechanisms suppress oxygenase activity, in some cases almost completely, and frequently increase the affinity of *in vitro* photosynthesis for CO_2 relative to the situation with C_3 physiology (diffusive supply of CO_2 to RUBISCO).

One group of these CO_2 -concentrating mechanisms does *not* involve covalent bond formation between CO_2 and an organic compound before RUBISCO activity. These mechanisms have considerable diversity, and can involve active transport of CO_2 , HCO_3^- , or H^+ as means of concentrating CO_2 . Such processes occur in many aquatic O_2 -evolvers, including all of the cyanobacteria, many of the algae, and some of the submerged vascular plants found in aquatic environments, and in a few terrestrial O_2 -evolvers, including all of the cyanobacteria, many of the terrestrial algae and lichens, and, among embryophytes, certain hornworts. There is an energetic cost of operating the CO_2 -concentrating mechanism; this has not been well defined for any mechanistic variant. In the case of cyanobacteria and dinoflagellates, the kinetic properties of RUBISCO mean that C_3 physiology is not an option for growth in an air-equilibrium solution. In some of the other organisms, the selective significance of a CO_2 -concentrating mechanism is quantitatively less clear (see Table 3).

A second group of CO_2 -concentrating mechanisms *does* involve covalent bond formation between CO_2 and an organic compound in the delivery of CO_2 from the environment to RUBISCO. These mechanisms are essentially restricted to vascular plants, with C_4 metabolism occurring only in certain flowering plants, whereas CAM (Crassulacean Acid Metabolism) is found in a wider range of vascular plants. Here the initial carboxylation reaction preceding RUBISCO is almost invariably catalyzed by phosphoenolpyruvate carboxylase (PEPC) to yield oxaloacetate, which is subsequently converted to malate or aspartate. In the case of C_4 metabolism, the formation of malate or aspartate occurs in mesophyll cells, with transfer of the C_4 acids to bundle sheath cells that contain RUBISCO but have little capacity for CO_2 exchange with the atmosphere. In the bundle sheath cells the C_4 dicarboxylate releases CO_2 , which is then fixed by RUBISCO, and the C_3 monocarboxylate residue is returned to the mesophyll, where it can be used to form more C_4 dicarboxylate. In C_4 plants the spatial separation of carboxylation and decarboxylation between two cell types involves only a temporal separation of seconds or tens of seconds. For CAM carboxylation to produce the C_4 dicarboxylate, malate and its decarboxylation to regenerate CO_2 occurs in a single cell type, but with an ~ 12 -h diel separation of carboxylation (in the dark) and decarboxylation (in the light). The energy cost of these biochemical CO_2 -concentrating mechanisms in addition to the 3ATP and 2NADPH required for the photosynthetic carbon reduction cycle in the absence of oxygenase activity is ~ 2 ATP for C_4 and ~ 3.5 ATP for CAM, giving a total per CO_2 fixed of

5ATP and 2NADPH for C_4 and 6.5 ATP and 2NADPH for CAM (see Table 3). C_4 plants are almost all terrestrial; while there are very large numbers of terrestrial CAM plant species (more than 20,000), there is also a significant aquatic representation (~ 100 species). In the case of terrestrial plants, C_4 plants lose less water in transpiration per unit carbon fixed than do C_3 plants, but with the similar or greater productivities; CAM plants are even more economical in terms of water loss, but generally have lower productivities when similar life-forms are compared.

Conclusions

The core reactions of primary photochemistry (RC1, RC2 in Bacteria and eukaryotes; bacteriorhodopsin and halorhodopsin in Archaea) show relatively little variation in structure or overall function, although there are significant differences (e.g., RC2 in O_2 -evolvers can dehydrogenate water). Similarly, the quinones, the cytochromes $b-c_1$ and b_6-f , cytochrome c , and ferredoxin also show little variation, as do plastocyanin (alternative to cytochrome c_6 in some O_2 -evolvers) and flavodoxin (alternative to ferredoxin in some phototrophs). ATP synthetase also shows great similarity among bacterial and eukaryotic phototrophs. There is more variation among the reactions upstream of the photochemical reactions that are involved in photon harvesting and excitation energy transfer.

The core CO_2 fixation reaction using RUBISCO in O_2 -evolvers and Proteobacteria is supplemented in some O_2 -evolvers by a diversity of CO_2 -concentrating mechanisms. In many aquatic plants there are CO_2 pumps not based on preliminary carboxylation and decarboxylation, whereas these reactions are found in C_4 and CAM. Bacteria other than Proteobacteria fix CO_2 via reactions not involving RUBISCO.

Glossary

Alternation of generations In plants, a reproductive cycle in which a multicellular gametophytic phase alternates with a multicellular sporophytic phase to complete the life cycle.

Autotroph An organism that obtains its nutrition by synthesizing organic substances from inorganic substances obtained from its environment.

Gametophyte In an organism with an alternation of generations, the haploid, gamete-producing phase.

Self-incompatibility A genetically based system that prevents fertilization of an egg by pollen that shares one or more alleles at a self-incompatibility locus. A mechanism to prevent self-fertilization in plants.

Sporophyte In an organism with an alternation of generations, the diploid, spore-producing phase.

Introduction

Defining Plant Biodiversity

Land Plants, also known as Embryophytes, include mosses, ferns, conifers, flowering plants, and related lineages. According to this circumscription, plants are mostly autotrophs that rely on photosynthesis, but some lineages include a small number of derived heterotrophs. Their life cycles include an alternation of generations, involving multicellular diploid and haploid phases of varying anatomical complexity, the sporophyte and gametophyte, respectively. The relative duration of these phases and the degree to which each phase is physiologically independent from the other differs among and, to a lesser degree, within the major plant lineages.

The land plants are variously divided into roughly a dozen major groups, and while consensus is building about the boundaries and membership of these groups and their relationships to one another, a consensus about the taxonomic rank of each group has yet to be achieved, and informal names remain in use. Informally, plant diversity is divided into four groups that include 10–12 extant lineages (Raven *et al.*, 2005). These are the nonvascular plants or bryophytes (mosses, liverworts, and hornworts), the seedless vascular plants (club-mosses and ferns including, horsetails, club mosses, and whisk ferns), gymnosperms (conifers, cycads, Ginkgo, and gnetophytes), and angiosperms, or flowering plants. Although some groupings are known or suspected to be nonnatural assemblages (i.e., the set of phyla described lineages that comprise an informal group do not necessarily share a unique common ancestor), life history and ecological characteristics unite their component members, and thus, we use these designations to structure the presentation of characteristics of plant biodiversity outlined below (*see* Plant Biodiversity Described).

Estimates of total plant diversity, including described and undescribed species vary by more than 50% because of two challenges: (1) Figuring out how many of the published names correspond to recognized, “good” species and (2) Estimating how much plant diversity remains undescribed or

undiscovered. Recent estimates of named plant species include roughly 380,000 species (Paton *et al.*, 2008), and an additional 10–20% of flowering plant species are thought to remain undiscovered (Joppa *et al.*, 2011). Because flowering plants represent more than 90% of all plants, it seems reasonable to extrapolate and suggest that a full catalog of current global land plant diversity would include perhaps 418,000–456,000 species. As noted, the great majority of this diversity occurs within flowering plants (approximately 352,000 species), followed by about 16,000 species of bryophytes, and 12,000 species of ferns and allies. Taxonomic knowledge of various groups is not equal, so while the catalog of conifer species may be nearly complete, the estimate for mosses may require substantial revision, as their diversity becomes better understood.

Plants as Units of Biodiversity, as Resources, and as Habitat

In nearly all terrestrial habitats, plants form the dominant features of the landscape. Satellite images reveal that most of what covers the land is plant biomass. Their dominance hints at the critical functional role that plants play in the global ecosystem; yet as living organisms, plant species also constitute units of biodiversity in their own right, and thus consideration of their unique biological characteristics, habitat requirements, and conservation status should be an integral component of research, discussion, and policy affecting local, regional, and global biodiversity issues. In the context of a reference on biodiversity, this may seem an unnecessary statement, however, vertebrate species continue to be the dominant focus of much of our conservation effort, with plants often relegated to consideration as habitat, food, or fixed carbon.

The complex web of interactions that constitutes our global ecosystem critically depends on marine and terrestrial photosynthetic organisms, including the members of the plant kingdom. Photosynthetic organisms are the planet’s primary

producers, harvesting light energy for their own growth, fixing carbon from the atmosphere into organic molecules, releasing oxygen to the environment, and ultimately sustaining life on earth. Globally, marine and terrestrial photosynthetic organisms fix approximately 100 billion metric tons of carbon annually and play a key role in maintaining the balance between fixed and atmospheric carbon, with roughly half of this amount being fixed by marine, and half by terrestrial photosynthetic organisms. Over the last decade, the impact of human activities on global carbon balance, and the cascade of impacts of ongoing climate change on ecosystems have become recognized as the leading environmental crisis facing our planet. In light of this, it is increasingly important that the potential for carbon fixation by photosynthetic organisms be maintained at the very least. Many human activities that threaten plant biodiversity, such as deforestation and habitat destruction or deterioration, also may decrease plant biomass, further exacerbating the carbon crisis. In consideration of global carbon cycles, vegetation is a central focus, and the emphasis tends to be on biomass and carbon sequestration capacity rather than biodiversity. While this perspective is reasonable given the critical role that plants play in this context, it is important to encompass all major plant groups within the framework of biodiversity policy, and practice. Therefore, in the presentation that follows, the biological properties of each group of plants are presented, with emphasis on those features that may impact issues relevant to discussions of biodiversity.

Plants and People

Human life and indeed all life on Earth ultimately depend on photosynthetic life forms. We depend on plants as sources of food for ourselves and for livestock, as sources of medicine, as raw materials for textiles and building materials, and as heating and cooking fuel.

The history of human civilization is inextricably linked to the history of agriculture, including the development of crops and livestock as food sources. It is estimated that only about 3000 flowering plant species have been used by people as food, and only 150 or so of these have been cultivated to any extent. Today, just six crops (wheat, rice, corn, potatoes, sweet potatoes, and manioc) directly or indirectly provide more than 80% of the human population's calories. The world's more highly industrialized regions depend on high energy input agriculture, in which crops are largely grown as genetically uniform monocultures. Such cultivation practices render these pure stands susceptible to pest and pathogen attack, and it is estimated that one-third of all crops are destroyed by pests.

Most of the global human population, however, lives in tropical and subtropical regions where relatively low input agriculture is most important. Further improvements in agricultural yields in these regions will have the greatest impact on global human welfare, where improving yields, nutritional quality, and disease resistance could greatly increase overall productivity.

Sources of wild germplasm remain of critical importance for future crop development and improvements required to feed the growing human population. Conserving the wild

relatives of our crop plants has become a primary concern of plant biologists the world over. Most plants are capable of interbreeding to some degree with wild relatives, and thus, traditional breeding can be used to introduce beneficial traits into cultivars. With genetic engineering tools, the ability to interbreed is no longer required to introduce traits into cultivars, thus removing limitations on species that can potentially be used as sources of genetic material. In addition, given the small fraction of plants that have been exploited as food sources by humans, the totality of plant biodiversity can be viewed as a potential source of new crops.

In addition to the major food crops described above, plants also make their way into our diets and our cultures as sources of beverages such as coffee and tea and in the form of spices, condiments, and oils.

Another use of plants that has and will likely continue to affect human lives is as sources of medicinal compounds. It is estimated that between 35,000 and 70,000 different species have been used as medicines by various peoples of the world and 80% of the global population derive almost all of their medicines exclusively from plants. Plants are extraordinary chemical factories: they produce a wide array of alkaloids, glycosides, and saponins that are the principal source of drugs used to prevent and cure illness in both traditional and Western medicines. Modern Western pharmacopoeia have derived approximately 7000 different medical compounds from botanical sources, and 120 or so of these are presently widely prescribed. Included among these are antimicrobial agents such as quinine, used in the treatment of malaria, and analgesics, including the alkaloids morphine and codeine, both derived from the opium poppy, *Papaver somniferum*. Glycosides produced by species of *Digitalis* have enormous value for the treatment of heart ailments, both in improving the action of a failing heart and in reducing a dangerously fast heartbeat. Plants are also sources of anticancer agents. Among these is the well-known rosy periwinkle (*Catharanthus roseus*) of Madagascar, which is the source of alkaloids used in the treatment of both Hodgkin's disease and acute lymphocytic leukemia. More recently, taxol, a drug originally derived from extracts of the Pacific yew (*Taxus brevifolia*), has become a key tool in the treatment of ovarian and breast cancers. These are just a few of the thousands of plant products that have been or are presently used to cure human diseases. There is no doubt that more species have immense untapped potential. Since tests for determining pharmaceutical potential are both time-consuming and expensive, and synthetic drugs continue to be unaffordable to a large proportion of the global population, it is likely that the dependence on local plant-based cures will continue.

The qualities of flexibility, durability, and strength, along with ready availability, make plant material such as wood an ideal source of building material. Wood and related products, including paper, are of enormous commercial importance. In industrialized nations these commodities account for a significant proportion of the total national consumption of goods. Plant species such as pine, spruce, hemlock, fir, redwoods, birch, beech, and oak are used as building materials in the temperate regions while mahogany, species of the family Dipterocarpaceae, bamboo, and rattan are used in the tropics, but are increasingly available in temperate regions as well.

A wide variety of other materials are also derived from plants, including the fibers used to weave cotton, linen, and jute, as well as latexes, resins, perfumes, and dyes. Finally, plants are also used by humans for their esthetic qualities. Ornamental plants in all their color and shape add beauty to our surroundings and are used in both public and private gardens, along roadsides in our cities, and as houseplants. In an increasingly urban environment, ornamental plants often constitute a rare link with the natural world.

In recent years, interest in the use of plants as sources of biofuels has risen, because such sources are renewable. However, production of biofuels requires high energy inputs and is likely to decrease the land area available for crop food production (and carbon sequestration), and thus the potential for these products to contribute to decreasing dependency on fossil fuels is mitigated by concerns about environmental impacts and net energy gains.

It is critical that while we exploit plants to satisfy our needs we continue to conserve and restore their natural habitats, if for no other reason than to preserve the homes that undoubtedly hold a wealth of other species with the potential to serve the needs of a growing human population.

Plant Biodiversity Described

Nonvascular Plants

Nonvascular plants (often referred to collectively as the bryophytes) include three groups: the mosses (Bryophyta), approximately 15,000 species; liverworts (Hepaticophyta), approximately 7500 species; and hornworts (Anthocero-phyta), approximately 250 species (Table 1). These three groups are characterized by their small stature, by the absence of specialized conducting tissues (i.e., xylem and phloem), which occur in other groups of plants, and by their life cycle. The conspicuous, dominant phase of the life cycle of these plants is the gametophyte (haploid) generation. Gametes are formed in specialized structures on the gametophyte called antheridia (containing male gametes) and archegonia (containing female gametes). Antheridia and archegonia may occur on the same gametophyte or on separate male and female gametophytes. Male gametes in the nonvascular plants have motile sperm and are dependent on water for dispersal to the female gametes, which are nonmotile eggs retained in the

archegonia on the gametophyte. Dispersal of gametes is thought to be extremely localized (less than 1 m). After fertilization, the diploid phase of the life cycle, the sporophyte, grows out of the archegonium, where it remains attached throughout its development, dependent on the gametophyte for most or all of its nutrition. Meiosis occurs in the sporangia, specialized structures of the sporophyte, resulting in the formation of haploid spores that are dispersed primarily by air currents. Spores are extremely small, tolerant of environmental extremes, and thus have the capacity to disperse over much greater distances than gametes. Many nonvascular plants also have the capacity to reproduce asexually as gametophytes, either by fragmentation or via specialized propagules called gemmae.

Ecologically, the three groups of nonvascular plants share their dependency on water for sperm dispersal, and thus bryophytes tend to occur where water is at least seasonally available and/or tends to accumulate. Among the richest habitats for bryophyte diversity are temperate and tropical cool, moist forests, and arctic and alpine habitats. Nonvascular plants grow on a variety of substrates, including soil and bare rock, and on other plants as epiphytes. On bare rock, they play an important role as initial colonizers. Peatlands are dominated by mosses in the genus *Sphagnum*. These unique and important ecosystems, while covering about 3% of the Earth's surface, represent a significant global carbon sink, estimated to contain 25–30% of the organic carbon stored in terrestrial soils. Although peatlands tend to have low net primary production (NPP) relative to many other terrestrial ecosystems, their success in carbon sequestration results from their slow rates of biomass loss through decomposition.

More than 60% of bryophyte families have worldwide distributions, occurring on all continents. Bryophyte species also tend to have wide geographic distributions: species that occur on more than one continent are common. Two processes have contributed to establishing present-day distributions. First, much of the diversity that we see today may be ancient, and present-day distributions may be the result of vicariance, or the splitting of a larger, once continuous range into smaller isolates. Second, especially in taxa that have originated more recently, present distributions are likely the result of long-distance spore dispersal. The role of ongoing dispersal in bryophytes is relevant to biodiversity research, because it has implications for structuring of genetic variation in these species. As suitable habitats become fragmented or

Table 1 The major groups of plants

Group	Estimated number of species	Percentage of globally threatened species
Hornworts	250	Not available
Liverworts	7500	Not available
Mosses	15,000	Not available
Club mosses (Lycophytes)	1000	30.8
Ferns	14,000	7.5
Cycads	283	82.8
Gnetophytes	65	2.5
Ginkgo	1	100
Conifers	630	55.8
Flowering plants (Angiosperms)	352,000	13.9

patchily distributed as a result, for example, of clear-cut logging on small and large scales, the potential for recolonization by extirpated bryophytes depends critically on dispersal and establishment, which are poorly characterized in these groups. Although we know that spores are easily carried by air currents, we know little about the factors that would limit recolonization, and only a handful of studies have examined patterns of gene flow in bryophytes. Another consideration in bryophytes that may be relevant to biodiversity is the relationship of taxonomic species described primarily on morphological and ecological criteria to biological species – units that are united by gene flow. The reduced morphology and absence of variation in traits related to gene flow are reasons to suspect greater decoupling of taxonomic species and biological species among bryophytes. As a consequence of our lack of understanding of evolutionary processes in these groups, a particular taxonomic species that may be considered common could comprise several cryptic, genetically isolated units, some of which may be critically endangered. Compounding this problem is the relative rarity of expertise in identification of bryophytes. While both academic and non-academic experts contribute to our knowledge of flowering plant biodiversity, in many areas, no local experts in bryophyte identification, professional or amateur, are found. Although the bryoflora of a number of regions is well characterized, the bryophytes are often far less thoroughly studied than vascular plants in the same region. One estimate suggests that nearly 30% of the global bryophyte flora remains undescribed (compared to the 10–20% unknown for flowering plants noted above). This shortage of expertise is reflected in the status of conservation initiatives in the bryophytes. As of 2011, the Red List for bryophytes consists of a list of 80 globally threatened bryophytes, of the 101 bryophytes assessed to date. Therefore, it is difficult to say what percentage of the world's bryophytes is at risk, or to make broad statements about global priorities for bryophyte conservation.

Seedless Vascular Plants

Seedless vascular plants include two major groups of plants: the Lycophytes (about 1000 species, including the club mosses and the genera *Selaginella* and *Isoetes*), and the ferns and allies (about 14,000 species; **Table 1**), including the horsetails (*Equisetum*, represented by about 15 species), whisk ferns, and other ferns. These lineages share a number of characteristics. They are the earliest set of lineages to have evolved vascular tissue (xylem and phloem). Vascular tissues provide structural stability that allows vascular plants (seedless vascular plants, gymnosperms, and angiosperms) to grow much larger than the bryophytes. The seedless vascular plants also lack seed formation, which distinguishes them from gymnosperms and angiosperms considered below.

Like the nonvascular plants, the seedless vascular plants have a free-living gametophyte generation that forms antheridia and archegonia, in which gametes are produced. Gametophytes in some groups are subterranean, nonphotosynthetic, and associated with mycorrhizae (fungal symbionts that occupy the roots). The gametophytes of most seedless vascular plants are inconspicuous and ephemeral relative to the sporophytes,

although in some lycophytes, for example, it may take 6–15 years for gametophytes to become fertile and produce a sporophyte. Male gametes are flagellate sperm, and therefore, as with the nonvascular plants, they are dependent on water for transport to the stationary egg. After fertilization, the diploid sporophyte grows out of the archegonium on the gametophyte, and the sporophyte eventually grows much larger than the gametophyte and becomes the free-living, dominant form of the life cycle. Meiosis occurs in sporangia on the sporophyte, producing large numbers of wind-dispersed spores that settle and germinate to form the next generation of gametophytes. This life history, in which the sporophyte is the dominant stage is a characteristic of all vascular plants.

The seedless vascular plants display a diversity of ecological tolerances, and occur in a range of habitat types, but still share some aspects of their ecology. The motile sperm remain dependent on moisture for transport to the egg, but the dominance and perennial habit of the sporophytes appear to have somewhat lessened the strength of selection for regular water availability, which appears to limit the range of habitats suitable for bryophytes. Living representatives of the Lycophytes are all herbaceous and mostly tropical. The two living genera of whisk ferns (*Psilotum* and *Tmesipteris*) are tropical and subtropical. Approximately 75% of other fern species are tropical and about a third of these are epiphytes, which grow on other vegetation. A few species of ferns are known only as gametophytes, while others do not appear to form sporophytes near their range limits. It may be that when ecological conditions are no longer favorable for some ferns, sexual reproduction is not possible. This suggests that rates of sporophyte production could act as an indication of habitat suitability in some species.

Among the seedless vascular plants, a number of families contain globally threatened species, according to the 2011 International Union for Conservation of Nature (IUCN) Red List for vascular plants. Twenty-six of 45 species of Lycophytes assessed to date are considered critically endangered, endangered or vulnerable. These numbers include 14 of 28 assessed species of the quillwort family, Isoetaceae. These small, inconspicuous plants most often occur in aquatic or wet terrestrial habitats in tropical and subtropical regions. They represent the nearest living relatives of ancient tree lycophytes that dominated the coal-forming swamps of the Carboniferous.

Among fern families, the Cyatheaceae, Ophioglossaceae, Loxomataceae, and Parkeriaceae all have in excess of 25% of their species listed as globally threatened. The Cyatheaceae is the family that includes the tree fern genus *Cyathea*. Tree ferns are conspicuous elements of tropical and subtropical montane forests. The Parkeriaceae includes only four species in the genus *Ceratopteris*, an aquatic genus of mostly tropical, edible floating ferns, some of which are cultivated for human consumption. The Ophioglossaceae includes three genera, among them the genus *Botrychium*. Members of *Botrychium* have unusual population structures, typically with very low numbers of mature sporophytes observed as scattered individuals. These ferns are perennials and may not produce aboveground structures every year. Gametophytes, which are subterranean in *Botrychium*, are rarely found, and thus the dynamics of sexual reproduction are not well-known.

Gymnosperms

The gymnosperms are conspicuous and important components of many terrestrial ecosystems. They include four lineages with living representatives, including the conifers (Coniferophyta; about 630 species), cycads (283 species in 11 genera), the maidenhair tree, *Ginkgo biloba* (the only species in the Ginkgophyta), and the gnetophytes (including three genera, *Gnetum*, *Welwitschia*, and *Ephedra*, totaling about 65 species; **Table 1**). Together, the gymnosperms and angiosperms constitute a uniquely derived group, the seed plants. The four lineages of gymnosperms (as well as the angiosperms) all form seeds, defined as mature ovules that contain embryos. As such, the seed plants represent a further shift in the importance of the sporophyte relative to the gametophyte generation. In all seed plants, the gametophyte is enclosed within sporophytic tissue and, thus, is no longer free-living at any time during its existence. Male gametophytes are packaged and dispersed as pollen grains, while female gametophytes are retained on sporophytes in ovaries. Pollen may be transferred to the vicinity of the ovules by wind or insects (e.g., some gnetophytes and cycads are likely beetle pollinated). Pollen tubes are formed, through which male nuclei are transported to the egg cells. After fertilization, the embryo develops inside the megasporangium wall, resulting in a seed that may be dispersed by wind or animal vectors. For example, the seeds of pinyon pine are dispersed by nutcrackers.

Although the cycads and *Ginkgo* have flagellate sperm, these are released from pollen grains after they reach the vicinity of the ovule, and thus, the seed plants do not require water for gamete movement. This opens up yet another set of habitats for these plants. Among gymnosperm lineages, ecological requirements are highly varied. Conifers, the most species-rich group of gymnosperms, are also the most diverse ecologically. Conifers play an especially important role in temperate and boreal forest ecosystems, where they are often the dominant tree species. In these regions, conifer species are also of significant economic importance and are managed for timber and paper pulp production. Overexploitation of this resource has impacted these ecosystems in numerous ways, impacting not only narrow endemics such as the burrowing owl of the Pacific northwestern USA but also other resources such as native fish habitats, including the spawning grounds of Pacific salmon.

The 1997 IUCN Red List for vascular plants indicates that all four phyla of gymnosperms include families with globally threatened species. The conifers include seven families with more than 49% globally threatened species. The single species in the Ginkgophyta, the maidenhair tree, *G. biloba*, is a relictual Asian species that was preserved in temple grounds in China and Japan and is not known to occur in the wild. A very large percentage of cycads (82.8%) are globally threatened (**Table 1**). The cycads occur in a variety of tropical and subtropical habitats. These relictual plants are cultivated as ornamentals and are threatened in part due to overcollecting.

Angiosperms

With more than 350,000 extant species, flowering plants represent more than 80% of plant biodiversity. They

essentially share the life cycle common to all seed plants, with the innovation of having reproductive structures contained in flowers and with further reduction in the gametophytic phase of the life cycle. The flowering plants have evolved a number of features that have been described as important in their radiation, including relationships with pollinators, which opened the way for diversification of floral structures that likely contributed to reproductive isolation among diverging lineages.

Flowering plants display a wide array of variation in ecology, life history, growth form, breeding system, and other traits that make them impossible to characterize as a group. Ecologically, flowering plants are more diverse than all other groups of plants described. They occur in virtually all terrestrial habitats, and in many of these, they are the dominant elements in the landscape. A number of flowering plant species have become adapted to aquatic habitats, while others have evolved tolerance to arctic, extreme desert, and even marine conditions.

The 1997 IUCN Red List for vascular plants lists nearly 300 families that include globally threatened species. Some generalizations about broad-scale patterns of diversity in flowering plants can be made, though regional, local, and taxon-specific patterns are also important in discussions of biodiversity. Because discussions of patterns of diversity most often consider all vascular plants (including seedless vascular plants and seed plants), these patterns will be considered in subsequent sections.

A number of features of flowering plants impact the way in which genetic variation is apportioned in nature, and thus these features impact not only the susceptibility of plant species to becoming threatened but also their potential for recovery. For example, the breeding systems of plants range from highly self-fertilizing to obligately outcrossing. Among outcrossing species, a variety of mechanisms exist to minimize the potential for self-fertilization. Chief among these are genetic self-incompatibility mechanisms, which are estimated to occur in as many as 50% of angiosperms. These mechanisms operate via the action of alleles at a single locus that must differ in paternal and maternal parents in order for matings to be compatible. Highly selfing species tend to display much higher levels of differentiation among populations than many outcrossing species and thus may show a greater tendency for adaptation to locally varying conditions. While inbreeding is generally viewed as having a negative impact on threatened species, plants that habitually inbreed are well adapted to do so. Thus, it is important to understand breeding systems in order to make well-informed conservation and management decisions.

Patterns of Plant Biodiversity

Measures of Biodiversity

Various measures are used to determine plant diversity, and these measures in turn contribute to prioritizing regions for conservation efforts. A simple measure of diversity is species richness. This measure refers to the number of different species in a given region. Although there are other more robust

measures of diversity, plant diversity studies are often based on the measure of species richness. The most species-rich regions of the world are in the tropics and subtropics. Species richness, while measuring the total diversity of a region, does not take into account the degree to which species occur only within a certain region, but these are likely to be correlated. For example, not only are the floras of the tropics the most species rich regions of the world, but also approximately two-thirds of the world's known vascular plants are restricted to tropical regions.

Species endemism measures the number or percentage of species that occur only within a particular defined region. Endemism is often used in assessing the relative contribution of particular ecologically or geopolitically defined areas to broader scale patterns of biodiversity (e.g., ranking the percent endemism of each ecoregion within a continent, or of each state or province within a country). Species that are endemic in a restricted ecological or geographic area (sometimes called narrow endemics, especially if they occur in low numbers within this restricted area) best fit the colloquial notion of rarity. However, while rarity suggests a high susceptibility to threats, and thus a need for conservation assessment, not all rare or narrow endemic species face imminent threats. As a tool for conservation efforts, descriptions of patterns of endemism are more useful when combined with an assessment of threats to persistence.

The description of biodiversity hotspots is meant to capture the combined effect of high endemism and high threat level on the biodiversity of a region, and serves as a tool for prioritizing conservation efforts (Myers, 1990). To qualify as a hotspot, a region must contain at least 1500 endemic vascular plant species, and have lost 70% or more of its primary vegetation type. Hotspots are priority areas for conservation of biodiversity beyond vascular plants, although the degree to which levels of endemism can be generalized to other taxonomic groups is not fully known.

Patterns of Endemism

Based on estimates from Myers (1990), as updated in Myers *et al.* (2000) and Mittermeier (2005) as many as 150,000 vascular plant species (more than 50% of the estimated total flora based on the author's estimates) are confined to 34 hotspots comprising only 15.7% of Earth's land surface. However, because 86% of the habitat in these hotspots has been destroyed (as of 2005), the hotspot flora is now confined to 2.3% of the Earth's surface. Seven hotspots contain more than 5000 endemic vascular plants each, and together these account for roughly one quarter of the world's flora (74,060 species). Note that nonvascular plants are not included in these determinations because of the lack of understanding we have of their taxonomy and global patterns of distribution.

The 34 hotspots can be grouped into several habitat types. Predominant are tropical forests, appearing in 15 hot spots, and Mediterranean-type zones, in five. Nine comprise islands or groups of islands, and almost all tropical islands fall into one or another hotspot. The seven "hottest hot spots" are predominantly tropical – Sundaland (Indonesia, Malaysia, and Brunei), the tropical Andes, the Mediterranean Basin,

Madagascar and associated islands, Brazil's Atlantic forest, the Caribbean Islands, and Cape floristic region.

The species-level analyses are complemented by an assessment of endemism among higher taxa such as plant families and genera. Madagascar and the surrounding islands possess eight endemic families and 310 endemic genera, Cape Floristic Province has five endemic families and 160 endemic genera, and New Caledonia has five endemic families and 107 endemic genera. Other hotspots containing few or no endemic families, with large numbers of endemic genera include the Caribbean with 205 endemic genera and Tropical Andes with 330. While the number of endemic higher taxa may rise or fall as our knowledge of relationships and boundaries is revised, these patterns of species richness and endemism, together with the broad destruction of habitat make these areas a high priority for conservation.

Threats to Plant Biodiversity

Intrinsic Features of Plant Species and their Interactions with Threats to Species Persistence

The effects of human activities now operate at such a global scale that it is likely that human activities directly or indirectly impact virtually all plant species to some degree. However, not all plant species are equally at risk, nor are all species equally susceptible to the action of a particular threat, even on a local scale. A variety of intrinsic factors have been suggested as affecting the degree of susceptibility of a species to threats, including life history features (e.g., annual vs. perennial, selfing vs. outcrossing, the presence and extent of seed dormancy, etc.), distribution and abundance traits, including local population size, range size, habitat specificity, and the extent of dependence on other organisms, for example, pollinators.

Population size can be an important determinant of the fate of a species, especially when considered in combination with the extent of a species geographic range. A species with a narrow geographic range and small population sizes will have an increased chance of all of its populations experiencing the same threat, and each small population will be at greater risk of extinction than in a species with a broader range and larger populations.

Specific biotic interactions can also be important for species persistence. Plants do not exist in isolation: in fact their survival often depends on other organisms. Many species of plants have evolved intimate relationships with a diverse array of organisms, without which they are unable to complete their life cycles. Symbiotic or mutualistic relationships with fungi, bacteria, insects, and birds are important for successful germination, growth, reproduction, and dispersal of propagules in many species of plants. For example, flowering plants that depend on one or a few species of animals for pollination and seed dispersal may become threatened with extinction in the face of a rapid decline in the population of these animals. Reduced seed set is the most direct effect of pollinator decline, yet indirect effects may also contribute to a decline in the plant population. For example, in the absence of pollinators, a higher percentage of seed may be set through self-pollination, increasing the expression of inbreeding depression.

Ultimately, loss of pollinators or disruption of pollination systems can cause plant extinction. A number of factors, including habitat alteration or fragmentation, grazing, introduction of alien pollinators, and the use of pesticides, can have drastic effects on pollinator populations. The plants most at risk from loss of pollinators are dioecious (species where male and female flowers occur on separate plants) or self-incompatible, those that have a single pollinator, and those that propagate only by seed. Once again, a plant species with a restricted range can be especially vulnerable to population fluctuations among its pollinators and seed dispersers.

It should be noted, however, that the effects of intrinsic features of plant species on extinction risk might be overshadowed by the interaction of such traits with extrinsic threats. For example, a threatened annual species with a persistent seed bank might be expected to have a lower extinction risk than a similar species that lacks a seed bank, because the seed-banking species can avoid unfavorable growing conditions by remaining dormant as seed. However, in the presence of an invasive species that can quickly colonize open patches, the longevity of the seed bank may not aid species persistence, and indeed may facilitate the establishment of invasive vegetation.

The Most Important Anthropogenic Threats to Plant Biodiversity

The greatest threat to plant biodiversity is habitat destruction, conversion, or degradation, which arises through the combined direct and indirect effects of agriculture (including crop production and cattle grazing), logging, and development. Overharvesting of individual species, invasion by exotic species and the effects of climate change round out the list of top threats to plant species persistence (Freville *et al.*, 2007).

Agriculture has had wide ranging and profound impacts on global ecosystems. The pressure for increased food production has done more to decrease plant diversity and to physically alter our surroundings than any other human activity. In addition to crop production, livestock grazing has also imposed drastic impacts on plant communities. The selective nature of grazing, combined with the limited tolerance of some plant species to grazing, has produced substantial shifts in regional species composition.

One of the most visible aspects of habitat degradation in natural landscapes is the spread of exotic, or occasionally native, invasive vegetation that alters or displaces native communities. Disturbances to plant habitats such as those described above increase opportunities for these invasions. The introduction and often widespread dissemination of alien species, such as Norway maple (*Acer platanoides*), kudzu (*Pueraria lobata*), purple loosestrife (*Lythrum salicaria*), and Japanese honeysuckle (*Lonicera japonica*), planted in environments where there are no natural controls or defenses, have been devastating.

The eventual impact of global climate change, the product of anthropogenically driven increases in atmospheric CO₂, is as yet unknown for most plant species and communities. Research on the effects of climate change on plants focuses on understanding the direct and indirect effects of changes in

temperature and precipitation patterns on species persistence. Temperature and precipitation shifts may directly affect species persistence via their physiological tolerances, but will also act indirectly by affecting interactions with competitors, pollinators, pathogens and pests, and all of these effects are the subject of ongoing research.

The current wave of extinctions resulting from systematic pressures imposed by human activities is eliminating 27,000 species each year, making this the sixth greatest mass extinction in the history of our planet. The principal factor determining the rate at which species are becoming endangered and extinct is habitat destruction and deterioration, especially in the species-rich tropics. The rain forests, which harbor this amazing diversity of species, are subject to destruction by exploitation and land clearing on an unprecedented scale. It is suggested that 60,000 tropical plant species will be at risk of extinction within the next 50 years. On a similar scale, of the 80,000 species of the temperate zone, about 8000 are threatened and several hundred endangered. At least 217 species of vascular plants and undoubtedly many species of nonvascular plants have gone extinct in North America over the past 500 years. Many extinctions have gone unnoticed because the species were not known to science. In the USA, old-growth forests of the Pacific Northwest, longleaf pine forests of the southeastern coastal plains, range-lands, grasslands and savannas, and wetlands – 33% of the species listed under the Endangered Species Act are dependent on wetlands – are all considered endangered or threatened ecosystems due to one or more reasons ranging from logging, to conversion to agriculture, and secondarily, to fire suppression or overgrazing and subsequent invasion by exotics.

Eleven hotspots have already lost at least 90% of their primary habitats while three have lost 95%, making conservation a high and immediate priority. Some hotspots have their endemic species concentrated in exceptionally small areas, making these species highly susceptible to extinction. The Eastern arc, New Caledonia, and the Philippines are especially significant in this regard. The criteria used to define hotspots exclude some of the most species-rich areas of New Guinea, Amazonia, and the Congo Basin because even though these regions contain rich endemic floras they also retain at least 75% of their primary vegetation, disqualifying them for hotspot status. Further, regions such as the Ethiopian Highlands, southeastern China, and northern Rwanda, where exceptionally rich floras face exceptional threats, are not sufficiently documented to meet the hotspot criteria. Thus, while it can be argued that hotspot analysis may be used to prioritize conservation efforts to areas where efforts will have the greatest impact, other poorly characterized regions and areas of high endemism must also be considered.

Natural Threats to Plant Biodiversity

In addition to the devastating effects on diversity by anthropogenic activities, natural catastrophes can also have negative impacts on plant diversity. Natural catastrophes such as natural fires, floods, hurricanes, landslides, and droughts occur at various times and scales in all parts of the world, but many of these events are projected or have already been observed to

occur with greater frequency or intensity as a result of rising CO₂. Thus, even these natural events are linked to human activity.

Many plant species and communities are adapted to disturbances such as fires and floods, and indeed, may depend on such periodic events for successful growth and reproduction. Floods, fires, and hurricanes and other natural events may provide the clearings or eliminate cover that otherwise prevent the establishment of species that are intolerant of shading or competition. In many landscapes, intermittent disturbance over variable spatial and temporal scales results in patchwork of habitat types or plant communities that sustain different species of plants, and therefore provide a mosaic of habitat types for nonplant species. However, the presence of human populations and infrastructure often leads to management practices that alter or eliminate natural disturbances, with unintended consequences for natural communities. For example, prairies and other grasslands, ponderosa and long-leaf pine forests often depend on frequent, low-intensity ground fires. Without these fires, these communities gradually change into other community types (e.g., grasslands into forest scrub) that are often less diverse, and can result in the need to recover the original ecosystem type through active management.

Diseases also pose threats to plant diversity. The recent rapid decline in *Chamaecyparis lawsoniana* (Port Orford/Oregon Cedar) across its range in northern California and southern Oregon has been attributed to a root rot disease caused by a fungus. Apparently, the spores of this fungus are transported mainly in the mud on tires of logging trucks. Other pests and pathogens that disperse along road systems include black stain root disease fungus and gypsy moth, all having had drastic impacts on plant diversity. Once again we see that a naturally occurring threat to a species can have an increased impact as a result of human activities.

Conservation of Plant Biodiversity

The consequences of loss of plant biodiversity for human welfare and global ecology are unpredictable and wholly irreversible. Hence, identification and protection of sites of high conservation value (i.e., biodiversity hot spots) is of high priority. A key limiting factor in our ability to identify targets for conservation is a lack of knowledge of the biodiversity present. While this gap is narrowing for vascular plants, nonvascular plants and other more cryptic forms of biodiversity remain understudied, adding value to novel approaches such as deoxyribonucleic acid (DNA) barcoding for estimating taxonomic diversity, and advancing the development of priorities that reflect the diversity of less known groups (Lahaye *et al.*, 2008).

Species are neither randomly nor uniformly distributed across the planet. Rather, they respond to environmental gradients, including climate, topography, and substrate. They further reflect historical contingencies resulting from patterns of colonization, phylogenetic history, speciation and extinction, plate tectonics, and other global processes. By paying attention to these processes, conservationists can identify areas and focal taxa of greatest importance for protection. There are

several criteria used in assessing the conservation value of natural areas. Species richness (or diversity), endemism, naturalness, rarity (extent of habitat), threat of human interference, amenity value, educational value, scientific value, and representativeness are some of the criteria considered when prioritizing conservation areas.

Destruction and fragmentation of natural areas are certain to lead to substantial increases in extinction rates. In some cases, *ex situ* conservation measures are warranted as a supplement or replacement for conservation on site. Although it is universally agreed that the most effective and efficient mechanism for the conservation of plant diversity is habitat protection or *in situ* conservation, it is also acknowledged that *ex situ* facilities can be critical in a comprehensive conservation program. *Ex situ* conservation programs supplement *in situ* conservation by providing for the long-term storage, analysis, testing, and propagation of threatened and rare species of plants and their propagules. They are particularly important for wild species whose populations are highly reduced in numbers, serving as an alternative to *in situ* conservation, as a source of material for reintroductions, and as a major repository of genetic material for future breeding programs of domesticated species. Methods of *ex situ* conservation can be classified according to the part of plant that is conserved – the whole plant, seed, tissues, or genetic material in culture. All these methods of *ex situ* preservation of live plant material require periodic regeneration and sexual reproduction of the stock. The latter requires knowledge of the breeding system and pattern of genetic variability of the species concerned.

Botanic gardens and arboreta have always played key roles in *ex situ* conservation, but the role of seed banks, including such ambitious endeavors as the Millennium Seed Bank, which targets seed banking 25% of the world's plant species by 2020 represent a more recent targeted global initiative. The most widely known function of arboreta and botanic gardens is to assemble and maintain a diversity of plant species. They also conduct and facilitate botanical research, especially in plant taxonomy and systematics. Arguably, botanic gardens make their most important contribution to the conservation of plant diversity through education and outreach, encouraging appreciation, and awareness of issues affecting plant diversity and of the contributions of plants to human well-being.

The Need for Further Study

Representatives of all groups of plants contribute to the health of the global ecosystem and to human welfare. As such, from a practical standpoint, any loss of biodiversity has the potential to negatively impact the future of the human population. A key limitation in the study of plant diversity is the training of professional and nonprofessional taxonomic experts in taxonomy of poorly known plant groups, including nonvascular plants, and diverse and challenging groups like the grasses and sedges, as well as taxa that have restricted distributions. As taxonomic expertise shifts away from academic institutions, our ability to train the next generation of plant taxonomists and expand our understanding of poorly known groups

may be hampered. Special emphasis should be placed on characterizing species that are thought to have potential for medicinal use. In addition, regions of the world that are highest in diversity, especially those regions that are most critically threatened, must be the target of a significant proportion of resources available for conservation. This can best be accomplished by training of additional highly qualified personnel and increasing funding to conservation agencies, including *ex situ* conservation programs. All of these initiatives will be most effective if they are coordinated by an international body that relies heavily on recommendations made by scientists and regional experts. It is only through concerted efforts such as these that we will be able to slow the loss of plant diversity around the world. As plants play such a vital role in the health of our planet and our species, it is of the utmost importance that we value and protect this diversity for future generations.

Glossary

Ecological restoration The Society for Ecological Restoration defines ecological restoration as an “intentional activity that initiates or accelerates the recovery of an ecosystem with respect to its health, integrity and sustainability.” The term “ecological restoration” refers to the practice of the discipline of “restoration ecology.”

Ecosystem services The benefits delivered or supplied to natural ecosystems. There are four main categories: provisioning, such as the production of food and water; regulating, such as the control of climate and disease; supporting, such as nutrient cycles and crop pollination; and cultural, such as spiritual and recreational benefits.

Ex situ conservation “Off-site conservation,” where the species or population is removed from the natural habitat and managed in a protected environment whether botanic garden, nursery, or stored as dormant seed or gametes for future propagation and use.

Extinction The end of an organism or of a group of organisms (taxon), normally a species. The moment of extinction is generally considered to be the death of the last individual of the species, although functional extinction may occur earlier as a species survives as a nonviable wild population.

In situ conservation “On-site conservation” of a species or population, in the natural habitat and subject to prevailing pressures of natural selection and interacting with other species (for instance, symbiotic fungi or pollinating insects) and local cultural influences. For agricultural germplasm, *in situ* conservation would include farmed areas.

Threatened species Any of those species that are facing a risk of extinction in the near future. The IUCN-SSC categories of Threat recognize three categories, depending on the degree to which they are threatened: Vulnerable, Endangered, and Critically Endangered.

Introduction

Plants are essential to life on earth – they are a fundamental component of global biodiversity, the key structural element to terrestrial ecosystems, the basis of all terrestrial food webs, and are essential to the functioning of both terrestrial and marine ecosystems. Plants provide a wide range of essential ecosystem services, including the production of oxygen, sequestration of carbon dioxide, the creation and protection of soils and watersheds (Isbell *et al.*, 2011; Kumar, 2011), and the provision of timber, fibers, food, forage, and natural medicines. Importantly, they are also of immense cultural value to our species; through art, medicine, and horticulture there is an ancient and intimate link between plants and people. Plant diversity, as part of a global trend for biodiversity, is declining (Butchart *et al.*, 2010). The impact of a growing human population, as measured through habitat loss and degradation, the overharvesting of species, the impacts of invasive species, pollution, and climate change, is reducing global plant diversity and accelerating natural rates of extinction. Accordingly, our options for establishing a sustainable future reduced are eroding.

Historically, plant conservation focused on the plight of high-profile threatened plant species, frequently “odd” endemics with unusual histories; now, the challenge is not only to retain an increasing number of threatened species but also to retain habitats and the ecosystem services they deliver. This work encompasses not only the conservation of flowering plants (angiosperms) but also the rapidly declining gymnosperms and the many species of fern, algae, and moss (Box 1). Plant conservation is largely terrestrial in its focus but also encompasses the conservation of freshwater plants and the

increasingly urgent conservation needs of coastal and marine plants, for instance mangroves and sea grasses (Box 2).

Plant conservation employs a wide variety of tools and resources to ensure the retention of current levels of plant diversity, the continuation of evolutionary processes, the provision of essential ecosystem services, and the avoidance of extinctions. This entails the deployment of a range of scientific, cultural, political, and economic tools. Importantly, plant conservation, while increasingly influenced by international and national policy, needs to be rooted in the cultures and customs of the locality, ultimately biodiversity will be retained because a community decides it is worth retaining, whether it is a Somerset meadow, a last patch of valley woodland in Yemen, or an expanse of Sahelian rangeland. This article provides a historical review of plant conservation issues and approaches and activities.

A History of Plant Conservation

Human societies have managed plant resources to ensure dependable access to timber, resins and gums, fruits, fibers, roots, and medicinals. This management has been driven largely by utility rather than any specific concern about the future of a species or a habitat. In many cultures, the retention of plant resources, whether grazing areas or sacred groves, also has a strong cultural and spiritual element. However, overharvesting is not a new problem; it is probably as old as our species. The cedars of Lebanon, *Cedrus libani*, now surviving as scattered and isolated groves in Lebanon, Syria, and Turkey, and covering probably less than 5% of their historical area, have been subject to a long history of management and

Box 1 The Conservation of salt water plant diversity

It is very easy to forget that the world's salt water ecosystems, the estuaries, coastal shelves, and oceans contain plants. Along the narrow coastal shelves human expansion has resulted in profound changes to habitats. Mangrove forests once covered more than 200,000 km² of tropical and subtropical coastlines; between 35% and 86% of this area has been lost over the past 25 years (Duke *et al.*, 2007). Mangrove forests provide a number of essential ecosystem services – they provide nursing grounds for commercial fisheries, they provide timber for construction and charcoal, buffer other coastal habitats from river-borne siltation, sea level rise, storm surges, and tsunamis (Mangrove Futures Project: <http://www.iucn.org/tsunami/>).

Over half (55%) of the biological carbon (or green carbon) captured in the world is captured by marine living organisms, the so-called blue carbon. The ocean's vegetated habitats, in particular mangroves, salt marshes, and sea grasses, while covering less than 0.5% of the sea bed are vital carbon sinks, assimilating more than 50%, perhaps as much as 71%, of all carbon storage in ocean sediments. Coastal waters account for just 7% of the total area of the ocean. However, the extraordinary productivity of coastal ecosystems, such as coral reefs and sea grass pastures, means that these small habitat areas form the basis of the world's primary fishing grounds, supplying an estimated 50% of the world's fisheries. (Blue Carbon Report: http://www.grida.no/files/publications/blue-carbon/BlueCarbon_screen.pdf)

A study of extinction risks for sea grass species (Short *et al.*, 2011) revealed that a third of the world's 72 species are in decline, with three species qualifying as Endangered (*sensu* IUCN). Sea grasses, like mangroves, provide invaluable ecosystem services, including providing habitat for coastal sea life, reducing shoreline erosion, and absorbing excess nutrients.

Marine phytoplankton are rarely featured in discussions about plant conservation; however, recent research indicates that the conservation of these marine organisms should be included in the agenda. Phytoplankton account for half of the planet's photosynthetic activity and drives marine ecosystem functioning. One study indicates that global phytoplankton is in decline (Boyce *et al.*, 2010), with potential implications for geochemical cycling and fisheries.

overexploitation for over 2000 years; indeed, the marker stones to Roman forest reserves have been found on Lebanese hillsides.

Although classical authors recognized the human-caused degradation of landscapes – for instance Plato in the *Critias*, describes the landscape of Attica as resembling “the wasted skeleton of a sick man” – the linking of human-caused habitat degradation and species loss was established only during the eighteenth century. This was largely as a reaction to catastrophic ecological changes following colonial occupation of oceanic islands such as Mauritius (Grove, 1996). For instance, one of the earliest *ex situ* conservation attempts can be attributed to Governor Byfield of St Helena, who, in the early eighteenth century, collected two seedlings of the then very scarce St. Helena redwood, *Trochetiopsis erythroxylon*, for cultivation in his garden on the island.

The extinction of the monotypic endemic *Franklinia alata-maha* in the USA helped to establish the concept of plant extinctions. Similarly, during the late nineteenth century and early twentieth century, a small number of species were assumed to have become extinct in the wild, notably *Ginkgo biloba* and *Amherstia nobilis*; both species were considered to be

Box 2 Crop wild relatives

The relatively few crops that provide most of the food we eat are the product of centuries of selection by breeders and the interaction of domestic and wild populations. Crop wild relatives (CWR) are the wild plant species that are genetically related to those crops, but unlike them, have not been domesticated. CWR are increasingly threatened by habitat loss and fragmentation, with the risk that invaluable genes could be lost to agriculture. However, these habitats are often ephemeral and not always incorporated into traditional protected areas portfolios.

CWR have provided novel genetic diversity that can improve productivity and crop quality, increase pest and disease resistance, and improve the tolerance of the crop to adverse conditions (Maxted and Kell, 2009). The need for these resources will only increase as agriculture spreads to new and more marginal territories and climate change impacts existing production lands and systems. The value of CWR resources has been proven. For instance, in the 1970s, the US maize crop was severely threatened by corn blight that destroyed almost US\$ 1000 million worth of maize and reduced yields by as much as 50% in 1978. The problem was quickly resolved through the use of blight-resistant genes from wild varieties of Mexican maize.

There are between 50,000 and 60,000 CWR in the wild. The conservation of these invaluable genetic resources will be delivered partly through gene banks; however, it is essential that the evolutionary dynamics of the populations are maintained through *in situ* conservation both in traditional nature reserves and on farmed landscapes. The Crop Wild Relatives Specialist Group is coordinating a global program for CWR conservation, working with a variety of partners including Bioversity International.

extinct in the wild and only surviving in Asian temple gardens. However, these appear to have been treated as isolated novelties and did not prompt any general concern or action from the botanical community about a growing extinction problem.

The broader environmental movement can be traced, in part, to the late nineteenth century protected area movement in the USA (the Yellowstone National Park Act of 1872) and the wilderness-inspired literature of Aldo Leopold. The 1960s saw the start of a public concern for the environment and the beginning of international and national structures for conservation. This concern led to a public and political environmental awareness of the 1970s as manifested through the establishment of Earth Day on 22 April 1970 in the USA and the Endangered Species Act of 1973. The Russian agricultural botanist N.I. Vavilov, during the 1920s and 1930s, promoted the value of crop relatives and wild species, now referred to as plant genetic resources, in supporting agriculture. The present concerns about plant conservation, both as a political and as a scientific issue, can be traced to a series of international conferences on plant genetic resources during the late 1960s and 1970s. The erosion of these resources was recognized as an urgent problem at a Food and Agriculture Organization (FAO) conference in 1961, and subsequently discussed by a joint FAO and International Biological programme (IBP) meeting in 1967, where the term “genetic resources” was introduced. The FAO Panel of Experts on Plant Exploration and Introduction led the debate on plant resources from the mid 1960s to 1970s, with the creation in 1974 of the International Board for Plant Genetic Resources (now Bioversity International). Crop wild relatives remain a global priority for

Box 3 The South Atlantic Island of Ascension – too late for habitat restoration?

On discovery in 1501, the island was a bare volcanic landscape with vast sea bird colonies supporting only 25 vascular plant species; of these, 11 are endemic. However, as a result of nineteenth-century garrison settlement, a large number of exotic plants were introduced for both agricultural and horticultural purposes. The effects of exotic species have transformed the original bare volcanic landscape of Ascension into a semiferrested one. Successive importations of plants from British and South African botanic gardens represented massive introductions of both plant species and associated invertebrate and fungal diversity. Consequently, the original upland *Marattia* fern thicket has been transformed into exotic woodland dominated by an introduced bamboo. In the middle altitudes, introduced *Casuarina*, *Araucaria*, and *Juniperus bermudiana* are forming open woodlands. The xeric lowland lava fields have been transformed into open woodland of *Prosopis juliflora* with introduced African grass species. The *Prosopis* is now encroaching on the turtle (*Chelonia mydas*) nesting beaches and threatening to expand onto the unique breeding colonies of Sooty Tern (*Sterna fuscata*). The transformation of terrestrial ecology has been massive and habitat restoration (*sensu strictu*) is no longer feasible; the priority should be to maintain and promote specific species and communities, for example, sea bird colonies, through the control of introduced predators (cats and rats) and herbivores (sheep and donkeys). The net effect has been an increase in total botanical diversity and primary productivity and the creation of a new synthetic ecosystem. However, in 2010, a specimen of the endemic fern, *Anogramma ascensionis*, commonly known as the parsley fern, was discovered, thought extinct since the 1950s, demonstrating the remarkable ability of some species to persist in highly modified landscapes. Ascension Island is developing as a novel ecosystem and as such indicates the future of many landscapes and ecologies.

conservation – their conservation and use being an essential foundation for sustainable agriculture (Box 3).

The United Nations Conference on the Human Environment held at Stockholm in 1972 is recognized as a significant starting point in global plant conservation. The Threatened Plants Committee (TPC) of the International Union for the Conservation of Nature (IUCN) was established in 1974 as a direct product of the initial “Red Data Book for Threatened Plant Species.” This network was designed to deal specifically with plant species outside of the remit of FAO. The TPC acted as the template for the subsequent evolution of the IUCN’s Species Survival Commission (SSC).

The discussions in the early and mid 1970s set the stage for botanic gardens and herbaria to take up leadership in plant conservation. The “Ark Paradigm,” the idea that *ex situ* facilities would hold stocks of threatened plants during a period of habitat degradation, was established as a working objective by botanic gardens in the 1970s. This attitude is manifest in the 1978 Red Data Book (Lucas and Syngé, 1978); for instance in the data sheet for *Dracaena ombet*, it was stated that “it seems too late for such a proposal (*in situ* conservation) to be worthwhile. Great efforts must now be made to bring the ombet into cultivation and maintain it safely in the botanic gardens of the world.” A notable conference in the late 1970s was “Extinction is Forever” (Prance and Elias, 1977); this conference attempted to assess levels of species decline and loss in the Americas and subsequently set the scene for many later developments in tropical forest conservation in the Americas.

Two conferences hosted by the Royal Botanic Gardens, Kew, in 1976 and 1978, established the agenda for botanic garden activities over the next two decades (Simmons *et al.*, 1976; Syngé and Townsend, 1979). As a result of the 1976 conference, the Threatened Plants Committee of the SSC of the IUCN was requested to establish a Botanic Gardens Conservation Co-ordinating Body: “to find out which threatened plants are in cultivation and where, and to keep botanic gardens informed of current conservation activities.” This need was reiterated at the First International Botanic Gardens Conservation Congress in Las Palmas, Canary Islands, in 1985 with the recommendation of the establishment by IUCN of the Botanic Gardens Conservation Secretariat (BGCS) later to become Botanic Gardens Conservation International (BGCI). In parallel to discussions on botanic gardens, a number of broader conservation references were published in the early 1980s that paved the way for the 1992 UNCED meeting – The “Earth Summit.” These included “The Brandt Report” (Independent Commission on International Development Issues, 1980), the Global 2000 Report (US Council on Environmental Quality and US Department of State, 1980), and the World Conservation Strategy (IUCN/UNEP/WWF, 1980). All three reports emphasized the linkages between the ongoing loss of species and habitats to human welfare and development needs, and subsequently paved the way for the Convention on Biological Diversity (CBD).

The CBD, ratified in 1992 at the Rio “Earth Summit,” is the major legislative influence on the conservation of biodiversity, directly influencing national activities through the requirement to produce and implement Biodiversity Action Plans. The main objectives of the CBD are:

- the conservation of biological diversity (Articles 6–9, 11, and 14);
- the sustainable use of its components (Articles 6, 10, and 14); and
- the fair and equitable sharing of the benefits arising from the use of genetic resources, including by appropriate (1) access to genetic resources (Article 15), taking into account all rights over those resources; (2) transfer of relevant technologies (Articles 16 and 19), taking into account all rights to technologies; and (3) funding (Articles 20 and 21).

The CBD created an opportunity for plant conservation to become increasingly linked with global biodiversity and sustainable development imperatives. Accordingly, The Global Strategy for Plant Conservation (GSPC) was established as a program of the Convention on Biological Diversity (Wyse Jackson and Kennedy, 2009). The GSPC was adopted by the Parties of the CBD in April 2002. The GSPC has had a profound impact on both the strategic and the practical implementation of plant conservation. The GSPC’s goal is to halt the continuing loss of plant diversity through five key themes:

1. Understanding and documenting plant diversity;
2. Conserving plant diversity;
3. Using plant diversity sustainably;
4. Promoting education and awareness about plant diversity;
5. Building capacity for the conservation of plant diversity.

Importantly, the GSPC established a direct link with the Millennium Development Goals, particularly in the areas of poverty reduction (Goal 1), combating disease (Goal 6), and promoting environmental sustainability (Goal 7).

The GSPC has been revised and new targets have been established for 2011–2020 that link with and support the 20 Aichi targets of the Strategic Plan for Biodiversity (2011–2020) (Table 1).

Although significant steps have been taken to establish plant conservation as a global priority, it could be argued that the practical implementation of plant conservation has not received sufficient attention. Although there have been significant and very important advances in global and national policy and strategy, new red listing initiatives, and the identification of important plant areas (IPA), practical “on the ground” implementation has been limited. The GSPC has been an extraordinary breakthrough for plant conservation; however, its implementation now needs to focus at a practical level.

The Distribution and Loss of Plant Diversity

The planet supports around 310,000 described plant species, with a potential total number of species estimated at possibly as high as 400,000 species (Govaerts, 2003). This diversity of species is concentrated into areas of unusual richness and exhibits variation at both a global and a regional scale. The taxonomic diversity of plants broadly correlates to latitude, and is generally the highest in the tropical and subtropical regions with high rainfall and mountains. Species richness and endemism were commonly used attributes for the identification of conservation priorities since they presumably reflected both the complexity and the uniqueness of ecosystems. Accordingly, early discussions identified tropical rainforests and oceanic islands as priorities.

In 1986, the International Union for the Conservation of Nature (IUCN) and the Worldwide Fund for Nature (WWF) initiated a project to identify major centers of plant diversity. The objectives of the project were: (1) to identify which areas around the world, if conserved, would safeguard the greatest number of plant species; (2) to document the many benefits, economic, and scientific that conservation of those areas would bring to society and to outline the potential value of each for sustainable development; and (3) to outline a strategy for the conservation of the areas selected. The project (Davis *et al.*, 1994, 1996, 1997) identified 234 areas of especially high species diversity, and correlates strongly with the listed 12 Megadiversity countries (*sensu* Mittermeier *et al.*, 1998). The “megadiversity countries” is based on three premises: (1) biodiversity is not evenly distributed among the world’s countries; (2) although international conservation priorities should be based on scientific information on biodiversity, it is governments that develop conservation policies and programs; and (3) a very small number of countries, lying wholly or partly within the tropics, contain a high percentage of the world’s species.

Myers (1988, 1990) identified conservation “hot-spot” areas, defined as areas of exceptional concentration of plant species, high endemism, and threatened with destruction. Myers initially identified 10 hot spots, all in tropical rainforest

areas. The analysis was expanded to 18, and subsequently, 34 biodiversity hotspots have been identified (Mittermeier *et al.*, 2004). This expanded portfolio of hot spots holds an estimated 150,000 endemic plant species, 50% of the world’s total. An analysis of projected habitat loss in 25 hotspots (Brooks *et al.*, 2002, 2006) indicates a very high risk of large-scale extinctions of endemic species. The Caribbean Islands illustrate many of the challenges facing plant conservationists (Box 4).

To identify priority areas for plant conservation at a national or a regional level, the concept of IPAs was developed. They provide a method for identifying and maintaining the richest sites for botanical diversity (algae, fungi, lichens, liverworts, mosses, and wild vascular plants). IPAs are selected with the intention of focusing on the conservation of the wild plant populations in these areas, and act as a subset in the broader context of Key Biodiversity Areas. The identification of IPAs is based on three criteria:

1. Presence of threatened plant species: the site holds significant populations of one or more species that are of global or regional conservation concern,
2. Presence of botanical richness: the site has an exceptionally rich flora in a regional context in relation to its biogeographic zone, and
3. Presence of threatened habitats: the site is an outstanding example of a habitat or vegetation type of global or regional plant conservation and botanical importance. IPAs can be identified within high-diversity hot spot regions and in the less diverse temperate regions with far fewer endemics, for instance the UK has over 150 recognized IPAs.

Barthlott *et al.* (2007) identified 20 global centers of vascular plant diversity where species richness exceeds 3000 species per 10,000 km², the majority being tropical, with the exception of the Mediterranean Basin, the Caucasus, the Cape, SW Australia, and the Himalayas. Within this group are five global centers where diversity exceeds 5000 species per 10,000 km² (Tables 2 and 3).

Human Influences on Plant Diversity

Habitat loss and degradation are the primary drivers for the loss of plant diversity. Historically, about half of the ice-free surface of the globe has been transformed, managed, or utilized by humans (Turner *et al.*, 1990), with an increasing proportion of the world’s primary productivity used by mankind (Haberl *et al.*, 2007). The Global Analysis of Land Degradation and Improvement (Bai *et al.*, 2010) estimates that nearly 24% of the world’s land area underwent degradation (as measured by declines in primary productivity) over the period 1980–2003. The Millenium Ecosystem Assessment estimated that about 60% of evaluated ecosystem services are being degraded or used unsustainably. In some regions, the loss of habitat has been near complete, for instance 90% loss of natural forest in Madagascar (Harper *et al.*, 2007).

The impacts of habitat degradation in the wet tropics have been successfully relayed to the general public; however, the

Table 1 The GSPC 2011–2020 Targets and linked targets for the Strategic Plan for Biodiversity (2011–2020)

<i>GSPC target 2011–2020</i>	<i>Relevant Target from Aichi targets of Strategic Plan for Biodiversity (2011–2020)</i>
1. An online flora of all known plants	T19. By 2020, knowledge, the science base and technologies relating to biodiversity, its values, functioning, status and trends, and the consequences of its loss, are improved, widely shared and transferred, and applied
2. An assessment of the conservation status of all known plant species, as far as possible, to guide plant conservation action	T19. By 2020, knowledge, the science base and technologies relating to biodiversity, its values, functioning, status and trends, and the consequences of its loss, are improved, widely shared and transferred, and applied
3. Information, research, and associated outputs, and methods necessary to implement the Strategy developed and shared	T19. By 2020, knowledge, the science base, and technologies relating to biodiversity, its values, functioning, status and trends, and the consequences of its loss, are improved, widely shared and transferred, and applied
4. At least 15% of each ecological region or vegetation type secured through active management and/or restoration	T5. By 2020, the rate of loss of all natural habitats, including forests, is at least halved and where feasible brought close to zero, and degradation and fragmentation is significantly reduced T11. By 2020, at least 17% of terrestrial and inland water areas, and 10% of coastal and marine areas... are conserved through effectively and equitably managed, ecologically representative and well-connected systems of protected areas...and integrated into the wider landscapes and seascapes T15. By 2020, ecosystem resilience and the contribution of biodiversity to carbon stocks has been enhanced, through conservation and restoration, including restoration of at least 15% of degraded ecosystems, thereby contributing to climate change mitigation and adaptation and to combating desertification
5. At least 75% of the most important areas for plant diversity of each ecological region protected with effective management in place for conserving plants and their genetic diversity	T11. By 2020, at least 17% of terrestrial and inland water areas, and 10% of coastal and marine areas...are conserved through effectively and equitably managed, ecologically representative and well-connected systems of protected areas...and integrated into the wider landscapes and seascapes
6. At least 75% of production lands in each sector managed sustainably, consistent with the conservation of plant diversity	T7. By 2020 areas under agriculture, aquaculture and forestry are managed sustainably, ensuring conservation of biodiversity
7. At least 75% of known threatened plant species conserved <i>in situ</i>	T12. By 2020 the extinction of known threatened species has been prevented and their conservation status, particularly of those most in decline, has been improved and sustained
8. At least 75% of threatened plant species in <i>ex situ</i> collections, preferably in the country of origin, and at least 20% available for recovery and restoration programs	T12. By 2020 the extinction of known threatened species has been prevented and their conservation status, particularly of those most in decline, has been improved and sustained
9. 70% of the genetic diversity of crops including their wild relatives and other socio-economically valuable plant species conserved, while respecting, preserving, and maintaining associated indigenous and local knowledge	T13. By 2020, the genetic diversity of cultivated plants and farmed and domesticated animals and of wild relatives, including socio-economically as well as culturally valuable species, is maintained, and strategies have been developed and implemented for minimizing genetic erosion and safeguarding their genetic diversity
10. Effective management plans in place to prevent new biological invasions and to manage important areas for plant diversity that are invaded	T9. By 2020, invasive alien species and pathways are identified and prioritized, priority species are controlled or eradicated, and measures are in place to manage pathways to prevent their introduction and establishment
11. No species of wild flora endangered by international trade	T4. By 2020, at the latest, Governments, business and stakeholders at all levels have taken steps to achieve or have implemented plans for sustainable production and consumption and have kept the impacts of use of natural resources well within safe ecological limits T6. By 2020, all fish and invertebrate stocks and aquatic plants are managed and harvested sustainably, legally and applying ecosystem based approaches, so that overfishing is avoided, recovery plans and measures are in place for all depleted species, fisheries have no significant adverse impacts on threatened species and vulnerable ecosystems and the impacts of fisheries on stocks, species, and ecosystems are within safe ecological limits
12. All wild harvested plant-based products sourced sustainably	T4. By 2020, at the latest, Governments, business and stakeholders at all levels have taken steps to achieve or have implemented plans for sustainable production and consumption and have kept the impacts of use of natural resources well within safe ecological limits T6. By 2020 all fish and invertebrate stocks and aquatic plants are managed and harvested sustainably, legally, and applying ecosystem based approaches, so that overfishing is avoided, recovery plans and measures are in place for all depleted species, fisheries have no significant adverse impacts on threatened

Table 1 Continued

GSPC target 2011–2020	Relevant Target from Aichi targets of Strategic Plan for Biodiversity (2011–2020)
13. Indigenous and local knowledge innovations and practices associated with plant resources maintained or increased, as appropriate, to support customary use, sustainable livelihoods, local food security, and healthcare	species and vulnerable ecosystems and the impacts of fisheries on stocks, species, and ecosystems are within safe ecological limits
14. The importance of plant diversity and the need for its conservation incorporated into communication, education and public awareness programs	T18. By 2020, the traditional knowledge, innovations and practices of indigenous and local communities relevant for the conservation and sustainable use of biodiversity, and their customary use of biological resources, are respected, subject to national legislation and relevant international obligations, and fully integrated and reflected in the implementation of the Convention with the full and effective participation of indigenous and local communities, at all relevant levels
15. The number of trained people working with appropriate facilities sufficient according to national needs, to achieve the targets of this strategy	T1. By 2020, at the latest, people are aware of the values of biodiversity, and the steps they can take to conserve and use it sustainably
T16. Institutions, networks and partnerships for plant conservation established or strengthened at national, regional, and international levels to achieve the targets of this strategy	T20. By 2020, at the latest, the mobilization of financial resources for effectively implementing the Strategic Plan for Biodiversity 2011–2020 from all sources, and in accordance with the consolidated and agreed process in the Strategy for Resource Mobilization, should increase substantially from the current levels. This target will be subject to changes contingent to resource needs assessments to be developed and reported by Parties
	T17. By 2015 each Party has developed, adopted as a policy instrument, and has commenced implementing an effective, participatory and updated national biodiversity strategy, and action plan

Box 4 The living dead

Plant conservationists face a challenge when dealing with the “living dead,” those species that survive as a few scattered, nonreproductive individuals, often surviving in an exotic dominated landscape without their pollinators or seed dispersal agents. Oceanic islands, having suffered massive levels of habitat loss, contain many examples of the living dead. For example both *Kokia cookei* from Hawaii and *Ramosmania rodriguesiana* from Rodrigues survive only as sterile single clones. Indeed, *K. cookei* survives as a grafted single clone. The endemic palm, *Hyophorbe amaricaulis*, survives only as a single tree in the Curepipe Botanic Gardens, southwest Mauritius. The single specimen has persisted within the botanic garden for over 50 years, with no regeneration recorded.

The Malvaceae illustrate many of the problems facing critically endangered island plants. In Hawaii, the two endemic Malvaceae genera *Kokia* and *Hibiscadelphus* are highly threatened. Of the seven described species of *Hibiscadelphus*, four species are known only from the original type specimen, three are Extinct, whereas *Hibiscadelphus woodii* survives with only four wild plants. Similarly, with the genus *Kokia*, two species are Critically Endangered, *K. cookei* survives only in cultivation, whereas *Kokia lanceolata* is Extinct. The endemic Hawaiian species of *Hibiscus* and *Abutilon* are all threatened.

As a result of intensive management, some “living dead species” are recovering; a good example is the case of the Round Island Bottle Palm, *Hyophorbe lagenicaulis*. As a result of invasive species control, specifically goat and rabbit, the wild population is recovering (Maunder *et al.*, 2002), while the potential exists to utilize cultivated stocks to compensate for the population bottle neck suffered by the wild population (Asmussen-Lange *et al.*, 2011).

Millennium Ecosystem Assessment Report (2005) indicates that desertification threatens over 41% of the Earth’s land area; between 20% and 70% of dry lands are already degraded, resulting in a decline in agricultural productivity, loss of biodiversity, and the breakdown of ecosystems. Environmental goods and services such as fuel wood, harvested gums and resins, medicinal and food plants, habitat for wild animals and grazing for livestock, soil fertility, and soil moisture for agricultural production are all being lost. Desertification currently impacts the livelihoods of some 250 million people in the developing world. These changes not only influence the livelihoods of millions of people but also have a direct impact on biodiversity – the loss of pasture or charcoal species, the loss of wildlife (e.g., antelope populations in the Sahel), or the near extinction of endemic passerines in Ethiopia (Spottiswoode *et al.*, 2009). In addition to the degradation of extensive rangelands, the arid regions are also suffering the loss of unique and often very localized habitats; these include the valley forests of Yemen (Arabia’s only closed canopy evergreen forest), the fog forests of Oman and Chile (the lomas of the Atacama), and the spiny forests of Madagascar. The arid areas contain some of the world’s most iconic plant species, such as the tree cacti of the neotropics, the baobabs of Africa and Madagascar, and important economic resources such as gum Arabic and frankincense.

Deforestation continues to be a major cause of decline for global plant diversity. Around 13 million ha of forest were converted to other uses or lost through natural causes each year in the decade 2000–2010, compared with 16 million ha per year in the 1990s. The net change in forest area in the period 2000–2010 is estimated at 5.2 million ha per year (an area about the size of Costa Rica), down from 8.3 million ha per year in the period 1990–2000 (FAO, 2010). South America and Africa continue to have the largest net loss of forest.

impact on arid lands and rangelands is less widely recognized (Reynolds *et al.*, 2007). Dry or arid areas cover 41% of the Earth’s surface and are home to over 1.7 billion people, including a large proportion of the world’s poorest peoples. The

Table 2 Numbers of plant species occurring in and endemic to each of the 34 hotspots (CI, http://www.conservation.org/where/priority_areas/hotspots/hotspots_revisited/key_findings/Pages/endemic_plant_species.aspx)

Hotspot	Plant species	Endemic plant species	Endemics as a percentage of world total
Atlantic Forest ^a	20,000	8000	2.7
California Floristic Province	3488	2124	0.7

^aHotspots overlapping, at least in part, with centers for vascular plant diversity by Barthlott *et al.* (2007).

Table 3 The five global centers for vascular plant diversity (*sensu* Barthlott *et al.*, 2007)

Center	Area (km)	Total spp.	Endemism spp.	% endemism	% protected
Costa Rica-Choco	78,000	12,500	5500	44	18.8
Tropical Eastern Andes	62,000	10,000	3000	30	19.1
Atlantic Brazil	50,000	6000	4500	75	6.3%
Northern Borneo	57,000	9000	3500	39	7.7
New Guinea	87,000	6000	2000	33	1.8

South America suffered the largest net loss of forests between 2000 and 2010, at about 4.0 million ha per year, followed by Africa, which lost 3.4 million ha annually. Asia, which had a net loss of forest of some 600,000 ha annually in the 1990s, reported a net gain of forest of more than 2.2 million ha per year in the period 2000–2010, primarily due to the large-scale afforestation reported by China and despite continued high rates of net loss in SE Asia driven by industrial oil palm plantation expansion.

The extensive conversion of wild habitats has resulted in changes to both the ecological and the taxonomic composition

of these areas. In many parts of the world, the change is almost complete; taxonomically and ecologically diverse wildlands have been converted to agricultural landscapes dominated by a small range of domesticates, for example, cereal monocultures replacing species rich steppes and prairie, oil palm replacing high-diversity lowland rainforest.

The Mediterranean biomes, as exemplified by the Mediterranean Basin and the California Floristic Province, are subject to increasing human population densities and urban spread and high levels of invasion by exotic species (Schwartz *et al.*, 2006; Underwood *et al.*, 2009). The Mediterranean Basin

has been subject to the near complete transformation of its original ecology, a process that can be traced back to the Neolithic. The contemporary pressures of intensive agriculture, urbanization, water extraction, tourism developments, changing fire ecology, and invasive species are accelerating the rate of change.

Spectacular patterns of degradation have occurred on oceanic islands. Oceanic islands are rich in unique endemic lineages and particularly susceptible to damage by invasive species (Sax and Gaines, 2008; Caujape-Castells *et al.*, 2009). Colonized Pacific islands were subject to profound environmental changes and high levels of avian, and presumably plant, extinctions following Polynesian settlement. One example, the Pacific island of Rapa Nui (Easter Island), underwent massive environmental degradation as long ago as 1200–800 BP. In the Caribbean, Atlantic islands, and Mascarenes, environmental degradation can be attributed to European colonial administration and the development of unstable and fragile economies based on plantation products. Colonial settlement would often focus on the clearance and agricultural development of the lowlands, with the retention, planned or otherwise, of upland habitats, albeit in a modified and fragmented form. It could be argued that the remote South Atlantic island of Ascension exemplifies the future of many island ecosystems changed beyond recognition as a result of invasive species (Box 5).

Some islands have suffered the virtual complete loss of original habitats. This can result from periods of over-exploitation over centuries. On Rapa Nui, no original plant communities have survived the Polynesian settlement and later colonial sheep ranching, the only surviving endemic tree, the toromiro or *Sophora toromiro*, is now Extinct in the Wild (Maunder *et al.*, 1999). On St Helena, only fragments of gumwood forest and montane tree fern thickets have survived, covering less than 1% of the island's land area (Maunder *et al.*, 1995). Plant conservation on oceanic islands often focuses on retaining and restoring fragments of the original biodiversity, sometimes the last individuals of a species, the "living dead" (Box 6).

As a result of deliberate introductions and as artifacts of the agricultural and horticultural industries, an increasing number of exotic species are growing in new territories and habitats. Although such introductions may in the short term increase local biodiversity, in the long term, such introductions are having disastrous impacts on both species diversity and ecological processes. Disastrous invasions include the impact of guava in Mauritius, prosopis in Ethiopia, miconia on the Polynesian Islands, and water hyacinth in the East African Rift Valley Lakes. Such invasions can have profound impacts on ecosystems for instance the invasion of the arid southwest of the USA by Mediterranean grasses has increased the impact of fires on succulent vegetations, with disastrous results. In addition, introduced diseases, such as chestnut blight in the USA, and pests, such as the New Zealand flat worm in the UK or the hemlock woody adelgid in North America, are impacting on plant diversity. Oceanic islands have in particular suffered from catastrophic declines in plant diversity as a result of invasive species, including the impacts of rats, goats, pigs, and ants, and diseases such as avian malaria killing bird pollinators.

Box 5 The Conservation of mosses

Mosses have developed during the past 20 years as a key component of plant conservation (Hallingback and Tan, 2010). Mosses and liverworts (Bryophytes) play a fundamental role in ecosystem services. Peat moss (*Sphagnum*) has a direct economic value as peat and plays a huge role in carbon sequestration as peat bogs by holding billions of tons of carbon as peat. Mosses play a key role in water cycles (particularly in temperate rainforests) and their value in medicine is being investigated. The Bryophyte Specialist Group is leading a global red list initiative and promoting their conservation. The Bryophyte Specialist Group has produced harvesting guidelines for commercially harvested species and is identifying centers of bryophyte endemism. A particular concern is the lack of trained moss taxonomists and ecologists in nations with rich bryophyte floras.

Recent studies of bryophyte floras have revealed unexpected concentrations of diversity that require protection. In Western Europe, the British and Irish Atlantic oak woods hold one of the richest bryophyte floras in the world. There are about 1770 bryophyte species in Europe; of these, 1150 are found in Britain. This equates to about 65% of the European bryophyte flora.

Box 6 Conserving the plant diversity of the Caribbean

The land area of the Caribbean hotspot is relatively small, a total land area of approximately 229,550 km²; the islands support a vascular flora of 205 native plant families, with 1447 genera and 10,950 species, with 183 endemic genera and approximately 7800 species of endemic vascular plants. A large proportion of the 183 endemic genera are represented by a single species (94), with 105 of the 183 endemic taxa restricted to a single island, Cuba, holding 65 endemic genera (Francisco-Ortega *et al.*, 2007; Maunder *et al.*, 2008).

Many of the Caribbean's endemic species are restricted to areas of unique geology, for instance the extensive areas of serpentine (nickel-rich) soil in Cuba; although these serpentine soils account for only 7% of Cuba's land area, around 920 of Cuba's 6375 plant species are endemic to that habitat, as are 18 monospecific endemic genera.

The Caribbean daisies, Asteraceae, are an overlooked and extraordinary flagship family for the Caribbean. The Caribbean holds almost one-third of the world's insular endemic Asteraceae genera (41 of the 136 genera, approximately 30%). A total of 32 of the 41 Caribbean endemic genera are single-island endemics, with Cuba holding 17, Hispaniola 11, and four endemic to Jamaica; of the 41 endemic genera, a total of 26 are unspecific. The endemic Asteraceae genus *Feddea* was first collected in Eastern Cuba in 1915 and was subsequently recorded from 16 historic locations. Recent fieldwork discovered only one location with a total of five plants. *Feddea* has been placed in its own monotypic tribe, the only tribe in the Asteraceae that is endemic to an island.

Found through Cuba, Hispaniola, Jamaica, and Puerto Rico are spectacular karst uplands or mogotes; these limestone hills are rich in endemic vegetation and often represent the last wild habitats in an increasingly agricultural landscape. The conservation of these karst landscapes is essential both for retaining endemic biodiversity and importantly for maintaining water supplies to major cities and towns in those islands.

Human activities, notably the combustion of fossil fuels and the subsequent release of carbon dioxide, are altering the composition of the atmosphere. The Fourth Assessment Report (AR4) of the Intergovernmental Panel on Climate Change (IPCC) stated that: "continued GHG emissions at or above

current rates would cause further warming and induce changes in the global climate system during the twenty-first century that would very likely be larger than those observed during the twentieth century". Global warming is expected to continue at ever-growing rates during this century and according to some scenarios the global temperature may rise by up to 6 °C (Richardson *et al.*, 2009). Understanding and preparing for the effects of climate change on plant species and communities is a major conservation challenge. The vast majority of conservation biologists accept the scientific evidence that climate change is proceeding and that we can expect profound changes to the planet's ecology and the delivery of plant conservation. However, there is still significant uncertainty on how species and ecosystems will respond to changing temperatures and importantly the changes to an ecosystem resulting from warmer temperatures. However, an increasing number of studies are indicating potentially large losses to biodiversity (Maclean and Wilson, 2011), the establishment of novel or new habitats or communities, and associated changes in ecosystem function (McClean *et al.*, 2005; Sommer *et al.*, 2010). Increasingly, adaptation to climate change is being built into conservation planning, for instance in Madagascar (Hannah *et al.*, 2008).

All of these damaging impacts are driven by one fundamental force: the increase in human population and the environmental demands of that population. The world population is currently estimated to be 7 billion. Current projections show a continued increase of population (but a steady decline in the population growth rate), with the global population expected to reach between 8.0 and 9.0 billion people by 2050. As a result of a globalized economy, volatile politics, and a fluctuating economy, it is difficult to predict where the next conservation challenge will arise. For instance, conservationists watched in alarm as illegal timber traders took advantage of the 2009 political upheaval in Madagascar to extract huge volumes of high-value *Dalbergia* and *Diospyros* timbers for the luxury furniture trade in China. In the past decade, big agro-business has become the main driver for forest clearance in SE Asia and Amazonia in response to the huge global demands for oil palm, beef, and soya bean.

Traditional medicine is based largely on plants and supports the primary healthcare of more people worldwide than 'conventional' or western medicine. Up to 80% of the population in Africa, for example, uses traditional medicine for their primary healthcare according to the World Health Organisation. The majority of species of plants in traditional or herbal medical treatments are harvested in the wild rather than cultivated. About 15,000 species of medicinal plants are globally threatened, the causes including loss of habitat and commercial overharvesting (BGCI – <http://www.bgci.org/files/Worldwide/Publications/PDFs/medicinal.pdf>).

Threatened Plant Species – How Many and Where?

We have no comprehensive list of the world's threatened plant species. However, steady progress is being made in assessing the conservation status of the world's plant species, through individual species assessments (for instance using the IUCN Categories of Threat) or by regional and global estimates.

What is clear is that the number of threatened species is increasing and the conservation challenge of retaining species diversity is becoming ever more demanding.

The most comprehensive survey of species decline was undertaken on behalf of the IUCN, using the old non-quantitative red listing system; this study indicated that about 33,400 plant species were threatened with extinction (Walter and Gillett, 1998), equating to about 10% of the world's approximately 300,000 described plant species. The current IUCN Red List, using the quantitative and universally applicable IUCN Categories of Threat, holds approximately 14,190 plant assessments (2011); of these, 9098 are classified as Critically Endangered/Endangered or Vulnerable. However, a far larger number of species have been assessed using a variety of other approaches. To expand the number of IUCN plant red list assessments for the proposed Barometer of Life project (Stuart *et al.*, 2010) to 38,500 records would cost an estimated 17,000,000 USD. The Sampled Red List initiative is an ongoing approach to gauge global trends in plant diversity through assessments of 7000 plant species.

Brummitt *et al.* (2008) estimates that about 20% of the world's known plant species are threatened with extinction, whereas Joppa *et al.* (2010), incorporating estimates of potentially new species, estimate that about 30% of all plant species are probably threatened.

Although a comprehensive global data set does not exist as yet, a range of studies indicates the scale of the conservation challenge. The South African National Biodiversity Institute (SANBI) has completed a red list for all 20,456 plant taxa found in South Africa. The Cycad Specialist Group of the Species Survival Commission has identified that 62% of all cycad species are threatened with extinction, largely as a result of overharvesting for plant collectors and the medicinal plant trade, habitat loss, and invasive pest species. *Encephalartos whitelockii* from Uganda is threatened as a result of ongoing construction of a hydroelectric scheme in its sole location, the Mpanga Gorge, whereas *Cycas micronesica*, native to Micronesia, is threatened by two exotic pests (the butterfly *Chilades pandava* and the scale insect *Aulacaspis yasumatsui*). Four cycad species are Extinct in the Wild, including three species of *Encephalartos* (*Encephalartos brevifoliolatus*, *Encephalartos nubimontanus*, and *Encephalartos woodii*) from South Africa. Similarly, a study of *Magnolia* species by Botanic Gardens Conservation International indicates that 131 species of the total 245 species are threatened with extinction (http://www.bgci.org/files/Media_Kit/magnolia_red_list.pdf).

An assessment of potential extinction rates for the Amazon based on ongoing habitat loss projects a loss of available habitat of between 12% and 24% with between 5% and 9% of the region's 50,000 plant species "committed to extinction," equating to approximately 2500–4500 species (Feeley and Silman, 2009). A study of species conservation issues on oceanic islands (Caujape-Castells *et al.*, 2009) estimates that of the 70,000 island endemic plant species, between 3500 and 6800 may be highly threatened with extinction (qualifying for IUCN categories Endangered or Critically Endangered).

Apart from the well-publicized estimates of loss from the tropics, it is evident that the European nations are losing species as a result of changes in habitat quality, land use, invasive species, and climate change. In contrast to areas in the

tropics, European plant conservation frequently focuses on the retention of traditional agricultural practices such as hay meadow management or transhumance. In Europe, although taxonomic diversity has increased as a result of new invasive plant species, the region has suffered an associated decline in phylogenetic diversity and an increased taxonomic and phylogenetic homogenization across the European regions (Winter *et al.*, 2010).

Responses to Loss of Plant Diversity

Conservation actions are implemented to reduce or reverse the damaging impacts of human-driven change on plant diversity. Management actions aimed at the conservation of biodiversity will vary in the scale of spatial, capital, and scientific investment, vary in the extent of impact (local, regional, or global) encompassing single species management through to continental scale wilderness retention. Increasingly, effective plant conservation will include economic and social focused actions; conservation will increasingly focus on the issues of land conversion and economic exploitation of plant products. The traditional schism between on-site activities (*in situ* conservation) and off-site activities with a species or genetic focus (*ex situ* conservation) is rapidly eroding and an integrated approach to plant conservation is dominating (*sensu* Falk, Millar and Olwell, 1996). A parallel development has been an increasing trend toward ecosystem-level conservation (Weeks, 1996) in both the temperate and the tropical regions. In addition, the linkages between biodiversity management and sustainable development have been given due recognition, particularly with regard to maintaining key ecosystem services for rural communities, whether it be pasture, access to medicinal plants, or the protection of watersheds.

The majority of the world's species will be retained through the "coarse filter" approach of habitat conservation; this could potentially conserve all levels in the biodiversity hierarchy and their interactions. However, many protected areas will require increasing management because of external influences impacting on ecological processes and resulting in changes in both community structure and composition. Protected area borders are permeable to disease, invasive species, poaching, civil unrest, and climate change. Protected areas have been established with the assumption that environmental conditions and community patterns/composition have been relatively stable for long periods in the past and will continue to be stable into the future. However, climate change studies indicate that habitats are loosely organized collections of species whose coexistence is dependent on their individual physiological limits. Accordingly, protected areas must be managed in the expectation of ecological change and may well require a supporting "fine filter" approach to catch those species knocked out by climate change or invasive pathogens. The need to manage species in the light of changing climate is being actively discussed, one controversial option, assisted migration, being the movement of species out of recorded or historical ranges with the assumption that climate change will render the existing populations nonviable.

The surviving major wilderness areas (Mittermeier *et al.*, 1998), large relatively undisturbed natural areas, offer the best

opportunities for retaining ecosystem and evolutionary processes. Beyond these areas, plant conservation will depend on a number of core skills: (1) the protection and active management of habitats to maintain plant diversity and ecological processes, (2) the management of individual plant populations to retain viable populations, and (3) managing the human context of plant conservation including sustainable use, cultural value, and public access.

Species recovery, the management activities required to halt or reverse the decline in a threatened species' population, can be best achieved through cross-disciplinary recovery teams applying the recommendations of a Species Recovery Plan. Such a program should have clear numerically based objectives utilizing, where appropriate, information from ecological, taxonomic, genetic, and social studies. A Species Recovery Plan provides a forum to bring all required expertise together to ensure a balanced integrated approach to species conservation.

Ecological restoration is a powerful tool for plant conservation; it has the potential to reinstate biological diversity and ecosystem processes and to provide a potent forum for community leadership in conservation. Restored lands, whether small habitat fragments or landscape-scale ecosystems, can support livelihoods, provide wildlife habitats, and provide a wide range of products and services. The potential is immense, with opportunities for post industrial and agricultural land use in the temperate regions and post forest clearance lands in the tropics. More than 2 billion ha worldwide are available for restoration and these lands represent an extraordinary opportunity to sustain ecosystem services and biodiversity, create corridors between surviving habitat areas, support local employment and agriculture and importantly, sequester carbon (WRI; <http://www.wri.org/map/global-map-forest-landscape-restoration-opportunities>). Restoration can take place at a local scale with strong community identity (for instance the St Helena Millenium Forest Project on the remote South Atlantic island of St Helena that is establishing a lost habitat the endemic Gumwood forest). At a larger continental scale is the Six State Restoration Project aiming to restore 1.1 million acres of habitat in Tennessee, Alabama, Missouri, Arkansas, Kentucky, and Illinois. In the wet tropics, the Harapan Rainforest restoration project, a partnership between the RSPB, Birdlife International and Burung Indonesia, which will restore 98,000 ha, shows the potential for large-scale habitat restoration.

Increasingly *ex situ* collections are an integral component of conservation programs for both wild taxa and crop genetic resources (Havens *et al.*, 2006). The world's *ex situ* plant resources encompass the traditional garden plots of the tropics, the intensive allotments, farms and gardens of Europe, and the global networks of seedbanks and botanic gardens. The world's network of plant genetic resource collections (e.g., seedbanks and field gene banks) contains relatively few species, but with high levels of infraspecific sampling. The CGIAR Eleven Centres together maintain over 650,000 samples of crop, forage, and agroforestry genetic resources in the public domain.

The most important 150 major crop gene banks are maintained, as part of the global network of CGIAR collections (<http://www.cgiar.org/impact/accessions.html>). These include the International Potato Center in Lima, Peru, with

over 5000 potato accessions, the International Rice Research Institute at Los Banos, the Philippines, with over 80,000 rice accessions, and International Maize and Wheat Improvement Centre in Mexico, with over 20,000 maize accessions.

Two recent developments illustrate a new sense of innovation and urgency for seed banking. The Svalbard Global Seed Vault (<http://www.regjeringen.no/en/dep/lmd/campaign/svalbard-global-seed-vault.html?id=462220>), situated in the arctic island of Svalbard, was opened in 2008, a converted old mine shaft in permafrost adapted as a global safety-storage for the storage of duplicate collections of seeds on behalf of other gene banks. The Seed Vault has the capacity to store 4.5 million different seed samples. The Millennium Seed Bank of the Royal Botanic Gardens, Kew, is the largest repository of wild collected seed for noncrop species (<http://www.kew.org/science-conservation/save-seed-prosper/millennium-seed-bank/index.htm>). Launched in 1996 and occupying a custom-built complex of seed vaults, laboratories, and public exhibition galleries, the MSB now holds over 30,855 species (including 12 Extinct in the Wild) and a total of 1.86 billion seeds. It currently holds approximately 10% of the world's flora and is working toward a 2020 target of holding 20% of the world's flora.

The largest collections of noncrop wild species are maintained by the world's botanic garden networks. There are approximately 2500 botanic gardens and arboreta in 148 countries worldwide and they maintain more than 6 million living plant accessions, with representatives of more than 80,000 species, almost one-third of the known vascular plant species of the world. In addition, the world's botanic gardens and botanical institutions hold a total of 142 million herbarium specimens (<http://www.bgci.org/resources/1528/>). Botanic gardens are increasingly being recognized as vitally important resources of horticultural skills and conservation biology research, which support the imperatives of *in situ* management of wild populations, and as readily accessible venues for public education. Botanic gardens have a fundamental role in public education as accessible venues for introducing the public, via compelling exhibits, to the imperatives of plant conservation and sustainable living (Maunder, 2008).

Plant conservation will be working with new tools, for instance the Reducing Emissions from Deforestation and Forest Degradation (REDD+) mechanisms (REDD "plus" conservation), allowing the sustainable management of forests and enhancement of forest carbon stocks, presents a key opportunity to protect forests while combating climate change and improving human well-being in developing nations. REDD+ provides a mechanism of monetary incentives for developing countries to halt or reduce forest loss, or restore forest. Although the implementation of REDD+ is not fully tested and remains controversial, some early initiatives show promise. Many of the pioneer projects encompass 1000 ha of forest and often support populations of iconic species (Harvey *et al.*, 2010, http://www.conservation.org/documents/redd/CI_REDD_Lessons_Learned.PDF), for instance the 13 million ha Xingu Basin project in Brazil. In Kenya, the Wildlife Works flagship "Kasigau Corridor REDD project" has secured over 500,000 acres of forest and protects the wildlife migration corridor between Tsavo East and Tsavo West National Parks. These early case studies indicate great promise but the long-term application of REDD+ remains to be tested.

Plant conservationists, faced with limited resources and a huge challenge of conserving many plant species, have started to identify the areas of greatest botanical diversity as a means of focusing resources. The IPA initiative of Plant Life has been remarkably successful (Plantlife, 2010, http://www.plantlife.org.uk/wild_plants/important_plant_areas/), identifying internationally significant sites for wild plants and threatened habitats. To date, teams have identified IPA in 66 countries, examples include 200 preliminary IPAs that were identified for North Africa and the Middle East and 1771 IPAs identified in 16 European countries.

Accelerating trends for both habitat loss and degradation have promoted discussion on the most effective responses to retaining both the taxonomic and the ecological components of biodiversity. Plant conservation strategies need to utilize a variety of complementary techniques, "integrated strategies" *sensu* Falk (1990). Recovery planning for threatened plant species is a relatively recent development, with the first US plant recovery plan initiated in 1979. Species recovery work for threatened plants is now widely adopted by national and regional plant conservation authorities.

The establishment of national plant conservation networks is playing an important role by promoting (1) national strategies and action plans for plant conservation in alignment with the GSPC and associated support and funding mechanisms, (2) assessing and monitoring national needs and priorities, (3) establishing an integrated approach to plant conservation, utilizing and promoting the available professional skills, (4) developing collaborative relationships and network with protected area networks, government agencies, parastatals, and NGOs, (5) initiating a national system for monitoring progress against GSPC targets and National Biodiversity Action Plans, and (6) institutional strengthening through locally focused professional training. National strategies using the GSPC framework have been produced for China, Ireland, Philippines, Seychelles, UK, and South Africa. Europe, through Planta Europa, has produced a regional plant conservation strategy. The delivery of these strategies is coordinated through national agencies and the national representatives for the Global Strategy for Plant Conservation. Examples of national plant conservation networks include the Center for Plant Conservation (CPC) in the USA, PlantLife in the UK, New Zealand Plant Network, Canadian Botanical Conservation Network, and the Australian Network for Plant Conservation. Some networks are regional for Planta Europa for Europe.

The CPC in the USA can be viewed as one model for a national network, based at the Missouri Botanical Garden, St. Louis, MO, USA, established in 1984 as a national network of collaborating botanic gardens with the clear focus on conserving threatened native flora. The CPC has promoted the utilization of both *in situ* and *ex situ* techniques. Fundamental to the effectiveness of CPC has been the availability of quality data on the distribution and status of botanical diversity; this has been heavily dependent on the activities of the Nature Conservancy's Heritage Programs. In addition, CPC has produced three keystone references for plant conservation, namely "Genetics and Conservation of Rare Plants" (Falk and Holsinger, 1991); "Restoring Diversity: Strategies for Reintroduction of Endangered Plants" (Falk *et al.*, 1996); and "Ex Situ Plant Conservation: Supporting Species Survival in

the Wild" (Guerrant *et al.*, 2004), and a new book on plant reintroductions (Maschinski and Haskins, *in press*). This has resulted in the development of working collaborations between protected area authorities, government agencies, and the adoption of population genetics as a working tool for botanic garden conservation activities. CPC works with 37 leading botanical institutions in the USA and through the National Collection of Endangered Plants holds over 700 threatened species and over 9,000,000 seeds.

A number of international networks have been established for wild plant conservation. The Species Survival Commission of the World Conservation Union (SSC/IUCN) has a number of international specialist groups for threatened plant taxa (e.g., orchids, palms, crop wild relatives, sea grasses, trees, and bryophytes), national or regional specialist groups (e.g., Korea, China, and Cuba), and regional red list authorities (e.g., East Africa).

As the human population grows and more land is converted to agriculture, the big challenge for plant conservationists will be retaining landscapes and habitats for wild plants. The future for plant diversity and its role in providing essential ecosystem services will depend to a large extent on negotiations over the use of land; these negotiations will take place in village assemblies, corporate board rooms, and government offices. How much wild land we retain and how much biodiversity we can maintain in working landscapes with ever-increasing human population densities will depend on our ability as plant conservationists to demonstrate and effectively communicate the value of plants and wild habitats.

Plant conservation stands at an interesting point in history; we are completing the botanical inventory of the planet, we are learning more about plants, their diversity, distribution, and status than we could have imagined 20 years ago, and we have an increasingly sophisticated, although still not complete, understanding of how plants support life and society. Yet this diversity is eroding at a rate unimaginable to previous generations – for instance we have witnessed the effectively "instant" loss of lowland SE Asian rainforests and the Brazilian cerrado to commercial agriculture.

Plant conservation is competing for resources and land in a world of increasing agricultural production (including expanding vegetable oil and biofuel production), the over-harvesting of high-value plant products (e.g., rainforest timber or medicinals), rampant urbanization, and accelerating environmental change from invasive species and climate change. Plant conservation could easily become focused on salvaging the lost. Future investment in scientific and practical activity should focus on the retention of viable habitat areas and the management of socially and economically important plant resources. Although a proportion of the world's plant diversity can be saved as "threatened species," the vast majority of plant diversity will depend on conserving viable habitat areas. A key strategy will be retaining extensive areas of wild habitats in a matrix of human-dominated landscapes; these surviving habitats will not only allow the retention of natural ecological processes but should also allow for the potential for migration in response to climate change.

There will need to be a continued investment in new tools for plant conservation. Key new research areas include advancing the ability to restore habitats and ecosystem services; although extensive restoration research has been

undertaken for temperate ecosystems, it is encouraging to see more work on tropical habitats. The management of habitat fragments and isolated plant populations will become increasingly important, specifically the techniques to maintain biodiversity in fragments and how to link isolated fragments in increasingly human-dominated landscapes. As plant diversity fades, so will traditional knowledge, as cultures become homogenized; hence, we are losing tools and approaches that will be valuable for the sustainable use of plant diversity.

Above all, the global investment in plant conservation needs to be scaled up; we have many of the tools we need but we need to dramatically expand the scope and impact of our work. Key to this is building both stronger institutions and professionals. Importantly, plant conservationists will need to play an influential role in the debates on land use, agricultural production, and habitat conversion, and importantly, effectively promoting plant conservation as a service for the public good. Although effective plant conservation will, in part be dependent on establishing effective policies, monitoring, and management tools, it will ultimately depend on society placing a real value on wild plants and landscapes.

Appendix

List of Courses

1. MSc Botanical Conservation, University of Plymouth, UK
2. Diploma in Plant Conservation Strategy, Royal Botanic Gardens, Kew
3. MSc Taxonomy and Biodiversity, Imperial College, UK
4. MSc and Diploma Biodiversity and Taxonomy of Plants, University of Edinburgh with Royal Botanic Gardens, Edinburgh, UK
5. MSc Plant Diversity, University of Reading, UK
6. MSc Ethnobotany, University of Kent, UK

Glossary

Alien plants Plant taxa in a given area whose presence there is because of intentional or accidental introduction as a result of human activities. Synonyms include exotic plants, nonindigenous plants, and nonnative plants.

Enemy Release Hypothesis The idea that alien species have a better chance of establishing and becoming dominant when released from the negative effects of natural enemies that, in their native range, lead to high mortality rates and reduced productivity.

Evolution of Increased Competitive Ability Hypothesis (EICA) A notion that posits that plants introduced to an environment that lacks their usual herbivores or disease agents will experience selection favoring individuals that allocate less energy to defense and more to growth and reproduction.

Fluctuating Resources Theory of Invasibility A theory, formulated for plants, that predicts that pronounced fluctuations in resource availability enhances community invasibility if coinciding with the availability of sufficient propagules to initiate an invasion.

Homogenization (Biotic) The addition to, and often the partial if not extensive replacement of, local biotas by alien species, which can result in decreased compositional turnover (β -diversity) of species between distant areas, in terms of both taxonomic and phylogenetic similarity.

Invasibility The properties of a community, habitat, or ecosystem that determine its inherent vulnerability to invasion.

Invasive alien plants Naturalized plants that produce reproductive offspring, often in very large numbers, at considerable distances from parent plants, and thus have the potential to spread over a considerable area.

Invasiveness The features of an alien organism, such as their life-history traits and modes of reproduction that define their capacity to invade, that is, to overcome various barriers to invasion.

Naturalized plants Alien plants that reproduce consistently and sustain populations over many life cycles without the input of resources or direct intervention by humans; they often recruit offspring freely, but mainly near adult plants, and do not necessarily invade natural ecosystems (cf. invasive alien plants).

Propagule pressure A concept that encompasses variation in the quantity, quality, composition, and rate of supply of alien organisms resulting from the transport conditions and pathways between source and recipient regions.

Range expansion The process whereby a species spreads into new areas (usually new regions, rather than local-scale movements) due to natural dispersal, though the expansion may be assisted by human-mediated changes to the environment. It differs from invasion in that human-mediated extra-range dispersal (i.e. across a biogeographical barrier) is not implicated; the concept can be applied to both native and alien species.

Technological innovations, driven by rapid increases in the global human population and requirements for diverse products and services from nonnative plants, have facilitated the large-scale (in terms of numbers of individuals, taxa, and foci of introduction) movement of plants to regions far beyond their natural dispersal range. This, together with widespread changes to disturbance regimes and the development of novel anthropogenic plant communities, has led to many plants becoming invasive in foreign environments. Plants carried to new habitats far from their natural ranges are very often introduced, intentionally or accidentally, as seeds; they arrive without key natural enemies that limit their performance in their natural range. For many reasons, most introduced species do not spread from planting sites, and cause no damage in the receiving environment. Many alien plants provide us with food, fuel, and timber, beautify our cities, and serve many other useful purposes without invading. However, some plant species that are able to spread in new

environments have profound influences in invaded ecosystems, and some are important contributors to habitat transformation and biodiversity loss in many parts of the world. This article focuses primarily on the ecology of those species that have invaded natural and seminatural systems. It explores how plants have been moved around the world, the factors that determine invasiveness and invasibility, how invasive plants affect invaded ecosystems, and the range of management interventions for dealing with invasive plants.

Concepts and Terminology

Terms such as *colonization* (or *colonizer*) and *invasion* (or *invader*) are sometimes applied with reference to species that reclaim their distributions rapidly following disturbance, or that quickly occupy new sites adjoining their original range following changes to factors that previously limited their

ranges; the former is used in an ecological context, whereas the latter conveys biogeographical context. Within any assemblage, species vary in their ability to persist under conditions of environmental change, and with respect to their ability to invade new sites. Most species occupy a reasonably fixed position on a continuum from colonizers or pioneers to later-seral species. The former typically undergo large fluctuations in population size whereas the latter are specialized for more stable environments where rapid population growth is unimportant. Such strategies are associated with distinctive suites of life-history traits.

Episodes of range expansion and contraction mediated by natural disturbances, interactions with co-occurring organisms, and restricted by natural barriers have driven the diversification of floras and the delimitation of the world's phytogeographic zones. Such events have also molded the biology of species in many important ways. Consequently, some plant species can respond rapidly to disturbances, and increase in numbers from populations comprising small numbers of individuals. This capacity is influenced by a suite of interacting traits such as aspects of the reproductive biology of the species. Importantly, human activities in the last few centuries have radically altered the opportunities and challenges for plant species with regard to dispersal, colonization, and persistence.

Humans have influenced the distribution of plants for millennia by altering opportunities for persistence, regeneration,

and spread. Such influences were originally mostly at local and regional scales. However, growing human populations and technological advances mean that humans now exert an influence on plant population dynamics not just locally, but also at a global scale. An important reason for this is that human actions have moved thousands of plant species to areas considerably beyond their normal dispersal ranges. Such changes have not only brought about quantitative changes to dispersal pathways but have also forged entirely new invasion pathways whereby plants are moved to new environments in new ways (Figure 1).

The study of weeds (plants, not necessarily alien, that grow in sites where they are not wanted and that have detectable economic or environmental impacts) has for centuries been directed at solving problems (how can weeds be killed or how can their effects on crops be reduced?) Colonization dynamics have been systematically explored by plant ecologists for over a century. The detailed study of the dynamics of plants introduced to regions far from their natural ranges is a more recent field of investigation (although Charles Darwin and other eighteenth century naturalists made important observations in this regard). Milestones in the study of such biogeographical events, termed invasions, have been Charles Elton's (1958) book *The Ecology of Invasion by Animals and Plants*, the international program on *The Ecology of Biological Invasions* (1982–1988) under the auspices of SCOPE (Scientific Committee on the Problems of the Environment) (Drake *et al.*, 1989), and, for Europe, the Delivering

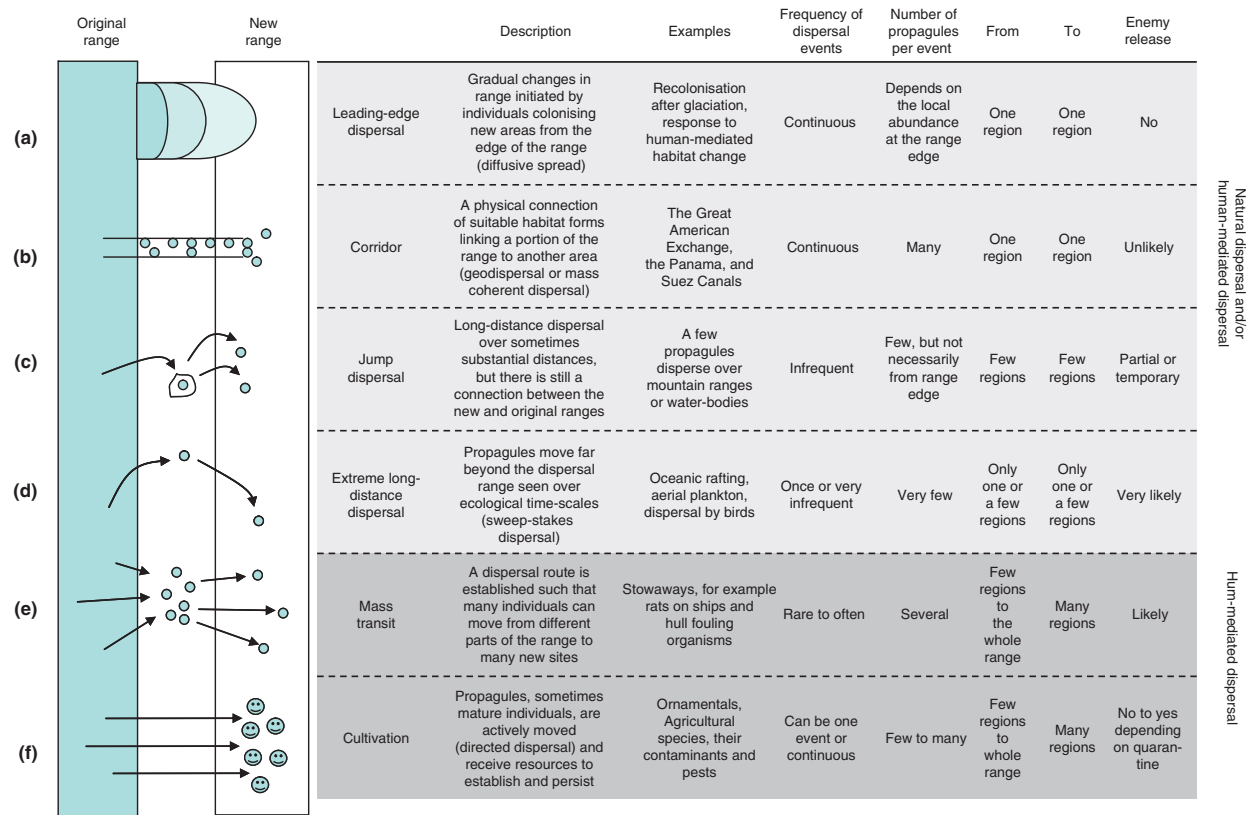

Figure 1 Extra-range dispersal categorized into six types of dispersal pathways. Reproduced from Wilson JRU, Dormontt EE, Prentis PJ, Lowe AJ, and Richardson DM (2009) Something in the way you move: dispersal pathways affect invasion success. *Trends in Ecology & Evolution* 24: 136–144, with permission from Elsevier. The cultivation pathway is the dominant pathway for most modern plant introductions.

Alien Invasive Species Inventories for Europe initiative (DAISIE, 2005–2008; <http://www.europe-aliens.org>). The primary international forum for research on plant invasions is the Ecology and Management of Alien Plant Invasions (EMAPI) conference series (Richardson *et al.*, 2010).

Humans have influenced the geographic ranges of plants for millennia, by shuffling their distributions and altering their abundances, both within and beyond their natural ranges. The extent to which such movements prior to the age of European colonialism shaped current distributions in Europe and Asia is often overlooked. Whether these range changes represent invasions is debatable since many changes were within or adjoining the natural ranges of such species. This is one reason for the blurred distinction between the categories colonizers and invaders in the older ecological literature. Examples of human-induced changes in the distribution of pines (*Pinus* spp.; Pinaceae) serve to illustrate the different categories of range expansion. The distributions of species such as *Pinus brutia*, *P. halepensis*, *P. pinaster*, and *P. pinea* have changed dramatically due to human activities over many centuries. *P. brutia* subsp. *eldarica* currently occurs in scattered locations from Azerbaijan to Pakistan. Genetic studies have shown that it occurs naturally only on a single mountain in Azerbaijan; the rest of its current range is due to humans who spread and managed this pine as a semi-domesticated land-race. Most of its known locations follow ancient trade routes along the path taken by Alexander the Great (356–323 BC). In North America and other parts of the natural range of *Pinus*, many native species have invaded meadows, abandoned lands, grazed grasslands, and other habitats where they did not occur before humans arrived. This is the case with many invasive species in their native ranges. Even within native ranges, species colonize human-modified habitats in which they did not evolve. Giant hogweed (*Heracleum mantegazzianum*) is an informative example. This species occurs naturally in forest fringes and tall-herb communities of a high altitudinal belt of the Western Caucasus where it grows at low densities among highly competitive stout herbs. It never occurs at levels of abundance that exist in the invaded range. However, in human-disturbed habitats in the lowlands surrounding these mountains hogweed creates large dominant stands with high cover and abundance, similar to those in many European countries where it invades. Thus, both patterns can be found in the native geographical range of the species, but they are strongly habitat-dependent (Pyšek *et al.*, 2007).

In other cases, range expansions have been augmented by human-mediated dispersal of seeds beyond their normal dispersal ranges. Most pines are equipped to be colonizers; when moved by humans to areas outside their natural range, many of these species become invaders, as shown, for example, by the invasive behavior of *Pinus radiata* and other pines in Australia, New Zealand, and South Africa.

Given the above-mentioned and other difficulties with classifying species that are alien to a given region, there has been much debate about terminology in the scientific literature. Only in the last decade has some standardization been achieved (see Glossary for a definition of the terms that are now most often used), although some concepts are still being actively debated.

The History of Alien Plant Invasions

Humans moved plant species beyond their natural ranges long before the dawn of the Age of Discovery and European colonialism. The frequency and pervasiveness of such early translocations were generally too limited to have resulted in widespread, damaging invasions. The voyages of exploration and the gradual settlement of the East and the New World by European powers (Britain, France, Germany, the Netherlands, Portugal, and Spain) heralded the start of a huge wave of translocations of plants and animals. Early colonizers transported mainly organisms from their homelands and actively assisted them in adapting (acclimatizing) to new regions. Many early botanical gardens established in colonies were essentially centers of introduction and acclimatization. This phase of ecological imperialism shaped the alien floras of many parts of the world that currently face the most severe problems with invasive alien plants. To cite but one instructive example: Plant introductions from Europe and Asia to South Africa between 1650 and 1806 reflected the need of Dutch colonists to cultivate a wide variety of agricultural and horticultural crops, mainly from their homeland in Europe and from the Dutch possessions in the East. Fifty or more crop plants were introduced within the first few years of European settlement, including many present-day weeds of agriculture. Subsequent waves of human immigrants, especially between 1800 and 1870, led to a surge in plant and animal introductions. Most of the plant species that now cause the greatest problems as invaders in South Africa arrived between 1825 and 1860, including hundreds of species of acacias, eucalypts and other plants from Australia. Other regions, such as North America or Australia, experienced a similar influx of alien plant invaders for the same reasons.

The magnitude and composition of the influx of alien plants to a given region during the colonial era was determined by many factors, including the geographical location and climate of the area, its cultural and economic links with colonial powers and other colonies, and special features of the region that influenced decisions on what types of plants to introduce. For example, the four regions of the world with a Mediterranean-type climate outside the Mediterranean Basin (California, Central Chile, southern and southwestern Australia, and the southwestern tip of South Africa) all received the bulk of their alien floras from the Mediterranean Basin. Smaller components came from other regions with which they had colonial ties, and even fewer from other regions. Current problems with plant invasions in these regions still reflect the dynamics of biological exchange during the colonial era, and the species composition of alien biota can still be, to a large extent, related to the time of discovery and the provenance of early human colonizers. More recent introductions from a broader range of regions are, however, becoming more prominent in alien floras; this is starting to blur the colonial stamp on invasions.

The rapid globalization of European trade routes starting in the eighteenth century led to a dramatic increase in the magnitude and diversity of the transcontinental movement in plants. Trends affecting plant invasions in the nineteenth and twentieth centuries are complex and region specific. There are important differences in patterns between Northern and

Southern Hemispheres, between eastern and western parts of the Northern Hemisphere, and between what are now known as industrialized and developing countries. The numbers of alien plant species that are becoming established are still increasing in most regions. Although new arrivals originate from a wider source area than the early introductions, they tend to arrive *via* more direct routes than in the past.

Among the fundamental factors that have affected invasions globally, especially in the twentieth century, have been (1) the improvement and expansion of transportation systems, both at an intercontinental scale, with the emergence of aircraft transportation and massive growth in shipping, and within regions (roads, railways, internal navigation canals, interbasin-transfer conveyance schemes, etc.); (2) massive habitat transformations and changes to prevailing disturbance regimes, considerably increasing the extent of ruderal habitats that are favorable for alien species and serve as foci for their further spread; (3) the introduction of large numbers of livestock to temperate grasslands of the New World dominated by caespitose grasses that lack the ability to withstand grazing pressure and were replaced by alien annual grasses preadapted to high grazing pressure; (4) widespread afforestation using alien tree species (the area of tree plantations – comprising mainly alien species of *Pinus*, *Eucalyptus*, *Tectona*, and *Gmelina* – doubled between 1980 and 1995 to cover 180 million ha globally); and (5) the increasing demand for alien plants for use in horticulture (North American seed and nursery catalogs offer more than 59,000 plant taxa for sale to national and international markets, including many known invasive species), and for other human uses. Developments in the twentieth century (especially the last quarter) that are particularly pertinent to plant invasions have included the increasing attention paid to scouring floras of previously underexplored areas for new useful plants; and the growth of agencies to facilitate the rapid transfer of germplasm of many multipurpose tree species for agroforestry and other purposes. Recent interest in the use of alien plants for biofuel production is likely to exacerbate problems. Most of the world's worst invasive plants reached the stage where they cause major damage only in the past four decades. It is now well established that plant invasions are a significant component of human-caused global change.

The Current Extent of Alien Plant Invasions

Plants are the best studied of all invasive organisms. Our understanding of invasion mechanisms and processes is based to a large extent on research on plant invasions. An analysis of published research on biological invasions showed that plants are the taxonomic group that is studied most frequently; almost half of all published case studies on invading species worldwide focus on plants. The two most frequently studied species are animals (zebra mussel *Dreissena polymorpha*, and Argentine ant, *Linepithema humile*), but among the 10 invasive species receiving most research attention, six are vascular plants (*Centaurea maculosa*, *Lythrum salicaria*, *Phragmites australis*, *Tamarix ramosissima*, *Spartina alterniflora*, and *Alliaria petiolata*) (Pyšek *et al.*, 2008).

Invasive alien floras include representatives of all main growth forms of higher plants (annuals, perennials, aquatic plants, epiphytes, geophytes, grasses, herbs, shrubs, trees, etc.). Alien plant invasions have affected aquatic ecosystems (estuarine, freshwater, marine, and wetlands) and most types of terrestrial ecosystems throughout the world, including arid systems, coastal systems, forests (boreal, temperate, and tropical), grasslands, savannas and woodlands (including mangroves), and shrublands. There are very few habitats globally that are not seriously affected by plant invasions; basically only habitats under extreme ecological conditions where plants are exposed to a strong stress, such as alpine habitats or acidic mires, etc., are rarely invaded (Chytrý *et al.*, 2008).

Though alien plant invasions are now a global phenomenon, they have been much better studied in some parts of the world than others. This is partly because of the history of introductions and dissemination within regions, and partly because of the global distribution of ecologists and the recent history of international scientific programs. At the end of the twentieth century most notable contributions to the literature on plant invasion ecology came from Australia, the Mediterranean Basin, New Zealand, the Pacific islands (especially the Galapagos and Hawaiian archipelagos), South Africa, the United Kingdom, and the mainland United States (especially California and Florida). Research from other regions, notably Europe, is now contributing key insights into plant invasion ecology (Pyšek *et al.*, 2008).

Some prominent examples of alien plant invasions worldwide (including those that have had severe impacts and those that have been particularly well studied) are:

1. The rapid spread of alien trees and shrubs of the genera *Acacia*, *Hakea*, and *Pinus* over large areas in fynbos shrublands in South Africa (Figure 2). These invasions threaten hundreds of native plant species with extinction, change fire and nutrient-cycling regimes, and considerably reduce streamflow from watersheds.
2. The rapid invasion of mesic and wet montane forests on the Society and Hawaiian Islands by the alien tree *Miconia calvenscens* (Melastomataceae), which transforms the forests, threatening many species with extinction.
3. The invasion of caespitose grasslands in North America's Great Basin by the European annual grass *Bromus tectorum* (cheatgrass; Poaceae) which is highly flammable and has increased the fire frequency from 60–110 years on average to 3–5 years. Cheatgrass invaded about 200,000 km² between 1890 and 1930, representing one of the fastest rates of aerial spread reported in the plant invasion literature (Mack, 1989).
4. The invasion of Europe by *Heracleum mantegazzianum* (giant hogweed). This species, introduced as a garden ornamental to the UK in 1817, escaped from cultivation very quickly, and has spread in at least 19 countries. It forms large dense stands in which few other species can survive (Pyšek *et al.*, 2007).
5. Widespread invasions of African grasses in the Neotropics and Australia, introduced to improve pasture yields. Prominent examples are *Andropogon gayanus* (Gamba grass) in tropical Australia, *Hyparrhenia hirta* (Coolatai grass) in South America, and *Pennisetum ciliare* (buffel grass) in the USA.

Figure 2 One of the most dramatic ecosystem transformations caused by invasive alien plants anywhere is that brought about by alien trees in South African fynbos vegetation where trees, especially those in the genera *Acacia* (*Acacia saligna*; top), *Hakea* (*Hakea sericea*; middle), and *Pinus* (*Pinus pinaster*; bottom) have changed species-rich shrublands into species-poor forests over tens of thousands of hectares. Photos, permission from David. M. Richardson.

6. The rapid spread of *Mimosa pigra* (mimosa; Fabaceae), a South American tree, to form dense thickets over about a million hectares of wetlands in Australia's Northern Territory. These thickets transform sedgelands into monotonous tall shrublands, and form an impenetrable understory in swamp forests, with profound consequences for biodiversity and for traditional Aboriginal food gathering.
7. The explosive spread of *Eichhornia crassipes* (water hyacinth; Pontederiaceae) in river and lagoons of West Africa and the Great Lakes of East Africa, especially in the past two decades, causing major disruption of fishing and navigation.

Which alien plant species are the most widespread or cause the most damage? There are numerous regional or national

lists of invasive alien plants, some of which provide data on areas invaded or rankings of the severity of invasions. However, since there are no generally accepted ways of quantifying when an area is invaded or when a species is invasive (as opposed to naturalized), attempts at compiling global lists of major plant invaders have generally been less than satisfactory. A global review was recently conducted of invasive trees and shrubs around the world. This study listed 622 species (357 trees, 265 shrubs in 29 plant orders, 78 families, and 286 genera) that are currently clearly invasive. Regions with the largest number of woody invasive alien species are: Australia (183); southern Africa (170); North America (163); Pacific Islands (147); and New Zealand (107) (Richardson and Rejmánek, 2011). For plants, the DAISIE initiative recently collated lists of plant species alien to Europe (DAISIE, 2009).

At least 5789 plant species are currently considered alien to at least one region in Europe, of which 2843 arrived from other continents. Considering only naturalized species, there are 3749 species of which 1780 are native to other continents (Lambdon *et al.*, 2008).

Invasion Processes

Plant invasions involve the following fundamental phases: introduction to the region by humans (intentionally or accidentally), establishment, population growth (sometimes accompanied by genetic adjustment), spread to new areas within the region (and often also outside the region *via* further dispersal by humans); interaction with the local biota and disturbance regime, and displacement of native elements. There are many ways of conceptualizing the various processes involved in invasion and interactions with biotic and abiotic features of the new environment. One may depict the various potentially limiting factors as a series of barriers (Richardson *et al.*, 2000). The simplest representation of such a model shows (1) a *geographic barrier*, which must be overcome by dispersal; (2) a *habitat barrier*, which requires preadaptation or genetic adjustment to the conditions of the new environment; and (3) a *biotic barrier*, which integrates the forces of predation, herbivory, competition, and interference that must be overcome in the new habitat, or the new mutualistic relationships that must develop. Additional complexity can be added by, for example, splitting the geographic barrier into two components (to account for factors limiting introduction

to the region and dispersal within the region, respectively), by adding a *reproductive barrier* (to account specifically for factors that potentially limit seed set), or by splitting the biotic barrier into components (e.g., to isolate the role of mutualisms). Figure 3 shows a refinement of the basic barrier for plants model to include insights from other taxa.

Stages of Invasion

Dispersal to a New Area

Important reasons for the intentional widespread translocation of plants include agriculture, forestry and agroforestry, botanical gardens, horticulture (including the commercial trade in seeds, bulbs, and cuttings, and urban gardeners using seed exchanges), and soil stabilization. Many plants have been moved around the world inadvertently, notably in ship ballast, with military transport, and as contaminants in fertilizers, hay and straw, grains, wool, and cotton. For the 622 woody invasive plants listed in a recent global review, those introduced for horticulture were most numerous (62% of species: 196 trees, 187 shrubs), followed by species introduced for forestry (13%), food (10%), and agroforestry (7%) (Richardson and Rejmánek, 2011). In Europe, 62.8% of all currently naturalized aliens were intentionally introduced. Ornamentals and escapees from horticulture account for the highest number of species (52.2%). Among accidental introductions, contaminants of seed, mineral materials and other commodities are responsible for 1091 alien species introductions to Europe (76.6% of all species introduced unintentionally) and 363 species are assumed to have arrived as stowaways (directly

Figure 3 A proposed unified framework for biological invasions, recognizing that the invasion process can be divided into a series of stages, that in each stage there are barriers that need to be overcome for a species or population to pass on to the next stage. Different parts of the framework emphasize views of invasions that focus on individual, population, process, or species. Reproduced from Blackburn TM, Pyšek P, Bacher S, *et al.* (2011), with permission from Elsevier. *Trends in Ecology and Evolution* 26: 333–339.

associated with human transport but arriving independently of commodity) (Lambdon *et al.*, 2008).

Naturalization

Empirical evidence shows that the chance of becoming naturalized, and later invasive, increases markedly with an increase in the number of propagules (any part of a plant that can give rise to a new individual, most often seeds, but also parts of vegetative reproductions such as bulbs and rhizomes) introduced, and with multiple introductions (including introductions at different times and from different source populations). More propagules reduce the likelihood of extinction and increase the chance of long-distance dispersal. Multiple introductions allow the incipient invader to sample a greater range of sites over space and time in the new environment and (since different introductions often originate from different source populations) improve the likelihood of introducing a genotype closely suited to local conditions. Also, multiple introductions increase the likelihood of forming novel genotypes that facilitate invasion, by hybridization of genotypes that may not meet in the native range; for this reason, some introduced populations may exhibit a greater genetic variation than is the case in the native range, although the opposite is more often true as a result of a genetic bottleneck. Successful establishment entails dealing with numerous physical, chemical, and biotic barriers. Many introduced plants are initially grown in small populations that are inherently susceptible to extinction due to chance events. To establish and persist, a population must exhibit $dN/dt > 0$ when N is small (the invasion criterion). If an introduced plant can deal with various reproductive barriers, and can reproduce in the wild without human assistance for a sufficiently long period of time to cope with local conditions, it becomes naturalized.

Spread

Invasion involves dispersal within the new area and population growth. Species in invasive alien floras show a wide range of adaptations for dispersal. Many species are dispersed by passive agents such as water or wind. A large proportion of the world's most widespread and damaging invaders, especially woody species, are dispersed by birds and mammals. More than 40% of invasive tree species and over 60% of invasive shrub species are dispersed by birds (Richardson and Rejmánek, 2011). The rapidity with which mutualistic seed-dispersal interactions establish suggests that vertebrate-dispersed plants have converged into generalized dispersal syndromes regardless of phylogenetic and geographical origins. Epizoochorous dispersal, mainly by cattle and sheep, facilitates the spread of many (mainly herbaceous) invaders. Vegetative reproduction is also important, especially in aquatic environments. For example, within the water hyacinth genus, the most invasive species (*E. crassipes*) is the one with the highest capacity for vegetative multiplication.

The dynamics of range expansion and population growth of invasive alien plants typically follow a standard pattern. There is frequently a time lag between the arrival of an alien plant in a new habitat and the start of widespread invasion. Examples include *Thlaspi caerulescens* (Brassicaceae), which was cultivated at Oslo Botanical Garden in Norway since 1814

and was first collected as an escapee in 1874, spread slowly until 1900, then expanded rapidly until it reached most of its present range in about 1945; *Mimosa pigra* (Fabaceae), which was virtually confined to small areas around Darwin in Australia for 80 years before exploding; *Melaleuca quinquenervia* (Myrtaceae), which showed no invasive tendencies for its first 50 years in Florida (United States); and *H. mantegazzianum* which was introduced to the Czech Republic in 1862, first recorded outside cultivation in 1877, but only starting to spread substantially some 70 years later (Pyšek *et al.*, 2009). Such lags are usually due to one or more of the following (non exclusive) factors: (1) the founder population may maintain a stable, small population until genetic adjustment occurs or essential mutualists (seed dispersers, pollinators, and mycorrhizal fungi) arrive (the extent of genetic alteration preceding or accompanying invasion has been studied for a few widespread invaders, for example, *Ailanthus altissima* in the United States); (2) some lags are probably explained by an initial shortage of safe sites, which have become more abundant as human-induced disruption of ecosystems has increased (increasing time also improves the chance of a potential invader encountering a safe site formed by a rare event such as a flood); and (3) populations spread slowly at their periphery but only show accelerated growth rates when there are many foci of growth. In some regions, the sudden start of spread may also be related to landscape transformation. In the Czech Republic (Central Europe), many species entered the exponential phase of invasion after World War II when political change resulted in large-scale transformations of landscapes that created many disturbed, eutrophicated habitats.

The lag phase is followed by a phase of sudden growth during which populations increase at an exponential rate (and generally become noticed as invaders). One reason for the increased growth rate (besides those mentioned earlier that may prevent its realization) is the typical two-phase pattern of spatial expansion. This involves the densest recruitment of offspring close to founder populations (neighborhood diffusion) and the establishment of isolated colonists through long-distance dispersal. As satellite foci grow in size through diffusion, often coalescing with each other and the founder metapopulation, more propagules become available for additional jump dispersal. With increasing numbers of growth foci, population growth and range increase rapidly. The rate of spread is frequently augmented by intentional or accidental movement of plants within the invasion arena by humans, thus creating additional nascent foci. This process, termed "stratified diffusion," has been documented for many plant invasions involving disparate plant taxa and environments and is evident at scales ranging from global, to regional, to landscape. The end of the exponential phase usually occurs when most optimum sites for invasion are occupied (or when successful control is instituted). Alien plant invasions may also follow linear trajectories (e.g., in the case of spread along rivers or coastal foredunes). Invasions in these habitats usually proceed as a wave front.

Spread rates reported for invasive alien plants vary considerably. Some examples of the fastest aerial spread are $5000 \text{ m}^2 \text{ y}^{-1}$ for *B. tectorum* (Poaceae) in North America, and $4000\text{--}13,000 \text{ m}^2 \text{ y}^{-1}$ for *Heterotheca latifolia* (Asteraceae) in the Georgia piedmont. For linear spread over large areas, the

fastest reported invasion is *Wedelia trilobata* (Asteraceae), which invaded 2500 km of Australian coast in 15 years, yielding the average rate of 167 km y^{-1} . At the local scales, the rates of linear spread vary from 970 m y^{-1} for *Fraxinus ornus* (Oleaceae) along a river in France; 76 m y^{-1} for *M. pigra* (Fabaceae) in wetlands in northern Australia; $21\text{--}31 \text{ m y}^{-1}$ for *Acacia cyclops* (Fabaceae) and *P. pinaster* (Pinaceae) in South African fynbos; and 14 m y^{-1} for *Ammophila arenaria* (marram grass; Poaceae) on coastal dunes in California (Pyšek and Hulme, 2005).

Invasiveness and Invasibility

A major thrust of studies on plant invasions in recent decades has been the search for traits that separate invasive species from noninvaders and features that distinguish invaded systems from those that are apparently able to resist invasion. Although the two concepts are intimately linked, the vast majority of studies have addressed the issues separately.

Invasiveness

Numerous studies have described the features of individual alien plant species that have enabled them to invade given areas. For example, the recipe for success for *Lantana camara* (Verbenaceae) includes the following ingredients: (1) dispersal of seeds for long distances by many native and introduced birds; (2) toxicity of its fruit for many mammals, which limits damage by herbivory; (3) its ability to resprout vigorously following damage (e.g., by trampling); (4) its ability to invade a wide range of habitats, including sites disturbed by alien mammals on islands; (5) production of allelopathic substances, which improves its competitive ability; and (6) its ability to flower profusely for long periods, thus attracting pollinators and ensuring copious seed set.

Attempts have been made to define invaders for particular regions (usually biomes or countries) or the entire world and to divide groups of plants into invaders and noninvaders. A notable early attempt to delimit traits of plants that enable them to become weeds or invaders was Herbert Baker's description of the ideal weed. Briefly stated, Baker's hypothetical superweed is a plastic perennial that germinates in a wide range of physical conditions, grows quickly, flowers early, is self-compatible, produces many seeds that disperse widely, reproduces vegetatively, and is a good competitor. Many of the world's most widespread invaders and weeds possess many "Baker characteristics," but none has all, and many notable invaders possess very few, if any, of these traits. Is there an optimum number of Baker's traits that confers invasiveness? The work of Mark Williamson and coworkers on British annual plants suggests that optimum weediness is realized in plants with an *intermediate* number of Baker characters (4 or 5 out of 7).

Plants that have performed best as alien invaders are clearly not evenly distributed among taxonomic groups. Among the angiosperms, two families are clearly overrepresented among the most widespread and damaging invaders of natural communities: Fabaceae and Poaceae. Other families that seem

particularly prone to contributing invaders of natural areas are Myrtaceae, Rosaceae, Salicaceae, and Tamaricaceae. The Asteraceae, the largest family of flowering plants, contributes many species to alien floras in most regions, but the family is not significantly overrepresented. Among invasive trees, the Fabaceae and in particular the genus *Acacia* *sensu lato*, and Pinaceae, particularly the genus *Pinus* are exceptional. For shrubs, the family Rosaceae (particularly species in the genera *Pyracantha*, *Rosa*, and *Rubus*) is also noteworthy.

Biological traits most often reported to be associated with invasiveness are those related to size, vigorous spatial growth, high fecundity, efficient dispersal, small genome size, and some physiological traits such as a high relative growth rate or a high specific leaf area. For example, differences in invasiveness among pine species (*Pinus*) can be explained using only three traits (seed mass, length of juvenile period, and interval between seed mast years), and if dispersal by vertebrates and characteristics of fruits are included, invasions of woody species can be reasonably predicted using this suite of traits (Rejmánek and Richardson, 1996). However, it has been shown recently that traits interact with other factors, namely the propagule pressure and the residence time of a species in the region (by comparing species with largely different residence time, we are likely to obtain biased results as some alien species are still in the process of filling their ranges in the new area), and that they directly affect invasion success rather at the more advanced stages of the invasion process. This points to the context-dependence of the role of traits in plant invasions; their importance changes with the stage of invasion, and those that confer invasiveness at some stage may not do so at other stages.

Many studies have attempted to gain an understanding of the life-history attributes of plants that makes them successful invaders by comparing traits of native and alien species or invasive and less invasive alien plants. Rejmánek (1996) considered perspectives from many of these studies and added many new insights to arrive at a general model of seed plant invasiveness based on recognized and assumed causal and correlative relationships between various traits, including those related to the native geographical ranges. This model is probably close to the limit of what can be achieved in defining invasiveness at a global scale. The most practical predictor of invasiveness is still whether the species has become invasive elsewhere (discussed later).

Two hypotheses that have received considerable attention recently in the quest to explain invasiveness in plants are the Enemy Release Hypothesis and the Evolution of Increased Competitive Ability Hypothesis. Both deal with the performance of alien plants in the absence of their natural enemies (see Glossary).

Invasibility

Charles Elton's (1958) *The Ecology of Invasions by Animals and Plants* (which, it should be noted, is heavily biased in favor of evidence on animal invasions) put forward the view that undisturbed native communities are not susceptible to invasion by introduced species. Recent debate on this topic has been rather futile since so few communities on earth are unaffected

by human activities. What has become abundantly clear over the past few decades is that disturbance, be it naturally occurring or human induced, is a fundamental driver of plant invasions. Irrespective of other factors that facilitate or limit invasions, the susceptibility of communities to invasion by alien plants increases with increasing disturbance up to a threshold, after which disturbance acts as a barrier. Useful insights into the types and magnitude of disturbance required to initiate and sustain invasions emerge from examining cases of invasion of pine trees (*Pinus* species) in many parts of the Southern Hemisphere. Most records document pine invasions in areas where the natural disturbance regime has been noticeably altered by humans. Changes to disturbance regimes have involved mainly increased or decreased herbivore pressure (grazing, browsing, and trampling), altered fire frequency, or mechanical clearing of vegetation. Different vegetation types differ in the type and magnitude of disturbance required to facilitate invasions. All records of pine invasions into native forests showed that severe disturbance is required to facilitate seedling recruitment and population growth. Invaded grasslands in Australia, New Zealand, and South Africa invariably have markedly changed disturbance regimes. The same applies for most invaded shrublands. The ultimate cause of increased invasibility due to disturbance in these cases is clearly the reduced competition from resident plants through the reduction in ground cover. Several pine species have spread into South African fynbos where the only disturbance is naturally occurring fire; intense fires and the dearth of vigorous plants immediately postfire combine to create opportunities for invasion. In general, intermediate levels of disturbance clearly make sites more vulnerable to invasion by pines, whereas severe disturbance usually prevents invasion. Naturally occurring disturbances where vegetation cover is removed are caused by factors such as volcanicity, slope instability, wind, and flooding; these are also important determinants of invasibility for pines.

Empirical evidence shows that certain communities are more susceptible to invasion by a wide range of alien plants than others. For example, the greater susceptibility to invasion of island communities (the more isolated, the more invulnerable) compared with mainland ones has long been noted. Islands where established alien species make up 40% or more of the flora include Bermuda, Hawaii, Ascension, Rodrigues, Tristan da Cunha, Lord Howe, and New Zealand (the figures for continental areas are much lower). Among the many reasons advanced to explain this are: (1) the species richness of islands is low (theoretically reducing the likelihood of an introduced species encountering a close competitor); (2) island floras have evolved in isolation, often without adaptation to high levels of competition, grazing, trampling, or regular burning; (3) the small size of islands means that the history of human intervention is concentrated (more intense disturbance); and (4) many islands were colonized very early and have been the crossroads of intercontinental trade (and thus were exposed to greater numbers of potential invaders).

Among other systems that seem particularly susceptible to alien plant invasions are riparian zones. In virtually every region, these zones are among the most severely invaded habitats. An important reason for this is the frequent disturbance from water-level fluctuation, including floods,

which disperses propagules and provides favorable sites for establishment.

Variation in how much a community, ecosystem or a region is invaded could be simply due to differences in the number of arriving aliens. Therefore, we need to ask not only whether the region has more alien species, but whether it is intrinsically more susceptible to invasions (Lonsdale, 1999). Because most invading species fail to establish, such intrinsic invasibility can only be determined if processes of immigration and extinction are considered. It is important to distinguish between two measures. Invasibility is the inherent vulnerability of a community to invasion and it is ideally measured as the survival rate of alien species introduced to the system, thus accounting for losses due to competition with resident biota, effects of enemies, chance events and other factors (Lonsdale, 1999). Invasibility differs from the level of invasion, which integrates the effects of invasibility, propagule pressure and climate and is defined as the actual number or proportion of alien species in a community, habitat, or region (Chytrý *et al.*, 2008). Therefore, relatively resistant communities can be invaded to a high level if exposed to high propagule pressure. Even relatively vulnerable communities will experience low-level invasions if propagule pressure is low.

Recent studies on invasions in European habitats (Chytrý *et al.*, 2008) showed that: (1) habitats differ considerably in their invasibility. The differences in the level of invasion between Central European habitats are mainly caused by inherent habitat properties and to a lesser extent by propagule pressure and climatic differences between regions. (2) Patterns of habitat invasion are consistent across different regions of Europe. The same habitats usually have either a high or a low level of invasion despite their geographical location. The most invulnerable habitats are those with fluctuating availability of resources, especially nutrients; most of these habitats are frequently or strongly disturbed.

These studies serve as an example of how information collected at a fine scale of invasions (proportion of alien species in the total number of species in a vegetation plot of tens to hundreds of square meters) can be translated to a regional and continental scale and provide information for risk-assessment. A European map of risk from alien plant invasions (Chytrý *et al.*, 2009) was constructed based on the levels of invasions in particular habitats and justified by previous work showing that the habitat identity is a suitable descriptor of the level of invasion (Figure 4).

Linking Plant Traits to Environmental Features

There have been important recent advances in our understanding of the determinants of invasiveness and invasibility. There is now a reasonable understanding, at least for some severely invaded regions, of the plant traits that are correlated with success as invaders and also the environmental features that mediate invasions. Further progress, certainly at scales of resolution that have value in management, will rely on the development of models that link plant traits with critical environmental features. Such models show that interactions between the various determinants of invasive success are

Figure 4 European map estimating the level of invasion by alien plants, based on the mean percentage of neophytes (species introduced after AD 1500) in vegetation plots. Within the mapping limits, areas with nonavailable land-cover data or insufficient vegetation-plot data are blank. Reproduced from Chytrý M, Pyšek P, Wild J, Pino J, Maskell LC, and Vilà M (2009) European map of alien plant invasions based on the quantitative assessment across habitats. *Diversity and Distributions* 15: 98–107, with permission from Wiley.

sometimes at least as important as the main effects. For example, in the case of pines invading forests, shrublands, and grasslands in the Southern Hemisphere, interactions between basic features of the environment, the features of the disturbance regime, and plant traits explain the different spread rates observed in different areas.

Modeling Plant Invasions

The use of models has considerably improved our understanding of invasions and how to deal with them. The many types of models that have been applied to plant invasions may be crudely grouped into three categories. *Simple demographic models* include exponential, logistic, logistic-difference, and stochastic models; they predict the future number of individuals in a population by making assumptions about the nature of population growth and by estimating the demographic parameters regarded as being important in

determining population dynamics. *Spatial-phenomenological models* describe plant–environment interactions using empirical data (without invoking ecological mechanisms); they include regression models, geometric models, and Markov models. *Spatial-mechanistic models* are based on independent estimates of ecological parameters affecting invasions; they include reaction–diffusion models, population dynamic meta-population models, and individual-based cellular automata models.

A particularly influential model in the study of invasions was that published by Skellam in 1951. He used a diffusion equation, combined with estimates of population growth, to show that invasion fronts advance at a constant velocity. Skellam's model, on which most subsequent invasion models have been based, did not incorporate long-distance dispersal, now known to be critically important for modeling the rate and variability of an expanding population front. Recent advances in mathematical modeling have facilitated the development of spatial-mechanistic models (notably individual-based,

cellular automata mixture models), which allow much more accurate modeling of all stages of plant invasions. Besides offering exciting opportunities for exploring critical processes in invasion, thus contributing to invasion theory, these models have important applications in management (Hui *et al.*, 2011).

Managing Plant Invasions

Plant invasions cause many types of impacts that justify management intervention. Impacts may manifest at the scale of populations, communities, or ecosystems. Some impacts of invasive plants are rapid and dramatic, such as those that transform entire ecosystems over a decade. Others are slow and cryptic, such as those involving the infiltration of pollination or seed-dispersal networks that may cause no dramatic effects but which have profound influences at longer time scales. Impacts may be measured using ecological or economic metrics (Pyšek and Richardson, 2010). An important implication of biological invasions is biotic homogenization. Winter *et al.* (2009) have demonstrated how the European flora is being homogenized (both phylogenetically and taxonomically) through a combination of plant extinctions and introductions/invasions (Figure 5).

There are three fundamental options for managing invasive alien plants: (1) prevention, (2) removal (eradication), and (3) ecological management. The appropriateness of different control approaches depends on the ecology of the invader and the invaded system, and on many socioeconomic issues.

Prevention

Despite pessimistic prognoses in the 1980s regarding the ability of ecology to predict plant invasiveness and invasibility at scales useful for management, important advances have been made. Various methods have been developed for screening introduced plants to assess the risk of them invading particular habitats. As mentioned earlier, a good predictor of invasiveness is whether a species has invaded other (similar) areas where it has a longer history as an alien. For example, 90% of invasive plant species in Australia are also invasive in other locations. A major problem with applying this concept to management or regulation is the time lag inherent in many (most) invasions – at what stage should the performance of a species be scored with regard to invasiveness? Also, many species are currently being introduced directly from their native ranges to many different areas simultaneously.

Removal

The options for controlling an invasive plant decline rapidly when the phase of exponential increase is reached. Management is clearly most effective when directed at removing invaders while they still occupy a small range and occur in small populations. Many potentially widespread invaders are effectively kept in check by various means of control at this stage. Removal is much less feasible once the invaders have spread over large areas, but is still attempted in some cases, usually when the damage the invaders cause overrides economic constraints and when other control measures are unavailable or impractical. For example, expensive, large-scale clearing of invasive pines and other alien trees in South African fynbos is warranted by estimated costs of reduced water production in the absence of control.

Ecological Management

Experience has shown that satisfactory control of plant invaders is usually only achieved when several complementary methods, including biological control, improved land management practices (e.g., through prescribed burning and modified stocking densities), herbicides, and mechanical methods are carefully integrated.

Confounding Factors – New Trajectories and Conflicting Human Perceptions

Invasive plants are being effectively managed in many parts of the world, albeit at a huge, and increasing, cost. The dimensions of problems associated with plant invasions are changing rapidly, and management strategies need to be flexible enough to deal with exigencies. Among the main reasons for changing trajectories of invasions are the following:

- The increasing magnitude and pervasiveness of global trade and free trade agreements means that more species are being introduced and in greater number (increased propagule pressure).
- The increasing availability and demand for alien plants for a wide range of purposes, especially for agroforestry and horticulture.
- Global change (including climate change, changed nutrient regimes, elevated CO₂, habitat fragmentation); although little is known of how all these factors affect invasions, especially in concert, most ecologists agree that these changes will exacerbate problems with invasive alien plants.

Figure 5 Changes in taxonomic and phylogenetic beta diversity, a measure of how species composition has changed in the past centuries, among European regions, based on comparison between current and past floras, and plotted for the effects of species extinctions (b) invasions (c) and combination of both (a). Red areas indicate the significant effects of both measures. Extinctions of native species lead to taxonomic and phylogenetic differentiation (current regional floras are less similar to each other than were original floras consisting of native species only) because they were local and have not occurred across the whole of Europe. Invasions lead to taxonomic and phylogenetic homogenization, with current floras being more similar to each other than was the case with original floras, because many alien species are widespread and occur in many regions. Since invasions considerably exceeded extinctions in numbers, they have an overwhelming effect if both processes are assessed in concert. Reproduced from Winter M, Schweiger O, Klotz S, *et al.* (2009) Plant extinctions and introductions lead to phylogenetic and taxonomic homogenization of the European flora. *Proceedings of the National Academy of Sciences of the USA* 106: 21721–21725, with permission from PNAS.

- Genetic engineering (GMOs, transgenic plants); genetically modified plants could acquire novel traits that may make them (better) invaders.
- Conflicts of interest; many alien plants are essential crops in some parts of the landscape/region/country and damaging invaders in other parts. Good examples are many tree species used in forestry and agroforestry, and *Echium plantagineum* (Boraginaceae), an important dry-season forage and a honey plant in South Australia, but an important weed of pastures in New South Wales. A major challenge is to develop objective methods for assessing the costs and benefits associated with our increasing dependence on alien species.

Glossary

Algae A group of aquatic plant-like organisms which obtain energy through photosynthesis.

Anticancer agent A chemical substance that is capable of bringing about a remission or cure of the family of diseases known as cancer.

Biosynthesis The biochemical process by which a plant produces molecules of utility or adaptation.

Cyanobacteria A group of photosynthetic prokaryotes, largely aquatic, which have an ancient evolutionary origin and exceptional capacity to produce bioactive natural products.

Cyanotoxin A group of toxins produced by various fresh water, marine and terrestrial cyanobacteria.

Cytotoxicity The ability of a chemical compound to kill cells in an experimental system, such as in a petri dish.

Drug development The process by which an early stage lead compound is developed using medicinal chemistry, pharmacology, toxicology and human clinical trials to become an approved pharmaceutical.

Natural product A compound, organic in nature (e.g., composed of carbon, hydrogen, oxygen and nitrogen), that is produced by a living organism for a purpose other than basic life functions, and provides some adaptive value to the producing organism.

Peptide A compound composed of several amino acids that are linked together by amide bonds.

Secondary metabolite A chemical substance produced for a reason other than basic life requirements and with some adaptive or defensive value.

Introduction

The intent of this article is to illustrate by example the enormous diversity of plant-derived natural products and their tremendous importance to human society. It is precisely this diversity of structure that has been, and continues to be, of such incredible value to the pharmaceutical and agricultural industries. Ultimately, this chemical diversity is rooted in the inherent biodiversity of our planet. Sadly, space limitations for this article limit this treatment to only a sampling of some of the most interesting examples. These have been chosen to exemplify several concepts: various chemical adaptations typical of particular plant groups, classes of compounds of utility to society, older examples deriving from ethnobotanical information, and modern examples resulting from methodical broad-based natural product screening programs.

It cannot be debated that the premier importance of plants to human existence is as a source of food and oxygen. Related to their serving a food function is the use of plant-derived materials as food additives to impart desirable taste or textural properties. Examples include the use of a class of biopolymer from red marine algae, the carrageenans, to stabilize emulsions in such diverse products as ice cream and beer, and the use of the sugar alcohol sorbitol, a product of the mountain ash *Sorbus aucuparia*, as a noncariogenic sweetener with humectant (wetting) properties in toothpaste. However, this article will focus on another property of plants; their ability to produce unique molecular entities with potent pharmacological effects in mammalian systems. Why do plants make such compounds? Given their complicated, often exotic, structures, they certainly expend considerable biochemical energy to produce these compounds. Although some hold that such compounds are vestigial in nature (previously served a

function that is no longer in evidence), there is excellent experimental evidence to support the idea that most, if not all, are produced with powerful adaptive functions, such as defense against potential predators, prevention of microbial infections, and inhibition of the growth of competing species.

However, complicating the above scenario somewhat is the quite recent recognition that a number of “plant-derived” compounds, including several of importance to human society (e.g., the camptothecins and vinca alkaloids, two classes of anticancer alkaloids), are in fact produced by endophytic fungi that live in specific association with their plant hosts. Indeed, in a number of other contexts, there is a growing recognition that microbial life forms are the actual producers of natural products which have been isolated from and ascribed to their macroscopic host plants and invertebrates (e.g., insects, sponges, and tunicates). Nevertheless, many of these adaptive metabolites still possess beneficial properties to the host macroscopic organisms, and by extension, to their microscopic symbionts, but serve to illustrate some of the complexity of relationships in the natural world.

Primitive peoples throughout the world make use of their indigenous flora as a source of medicines. Through the process of trial and error, these cultures have examined and discovered many plants that produce unique molecular entities with valuable biological properties. The fields of “ethnopharmacology” or “ethnomedicine” seek to obtain new pharmaceutical leads from a study of the native medicines of these primitive peoples, an approach that has been highly successful and resulted in such compounds as aspirin from willow bark (*Salix*), the anticancer alkaloid vincristine from the Madagascar periwinkle (*Catharanthus*), and the antimalarial sesquiterpene artemisinin (qinhaosu) from the Chinese herb *Artemisia annua*.

Beginning in the 1950s, comprehensive evaluations of the unique constituents of plants were undertaken. In the USA, these earliest efforts were coordinated largely by the National Cancer Institute (NCI), and so necessarily had a focus on anticancer properties. Assays for potential anticancer activity at that time were run in intact animals (*in vivo* evaluations). Although even the most modern drug-development efforts require evaluation of a drug for efficacy and toxicity in animal systems, this usually occurs only after a candidate pharmaceutical has shown the requisite property in isolated biochemical and cell-based screens. Consequently, current *in vivo* evaluations occur only on a very small fraction of the most promising candidate pharmaceuticals. In contrast, the early screening efforts of plant extracts used *in vivo* techniques; consequently, they were very slow, expensive, and, perhaps worst, used test animals in large numbers.

In the late 1970s, and gaining broad acceptance in the 1980s, a major shift away from whole animal primary screening was achieved with the introduction of cell-based screening. In the cancer effort, this largely had the endpoint of cytotoxicity to cancer cells grown in small petri dishes or, later on, 96-well trays. Expansion of this idea was undertaken by the NCI wherein extracts and compounds have been evaluated for their level and profile of toxicity to 60 different cancer cell lines. The cell lines were chosen so as to represent cancers affecting nine different organ types and have been quite useful in detecting new cytotoxins as well as giving information about their molecular mechanism of action.

The past 15 years has seen a growing departure from even cell-based assays. Over the past 40 years, there have been tremendous advances in understanding at a molecular level the causes of many diseases, including cancer. This has translated into assays that screen for compounds or extracts that interfere with specific enzymatic reactions or protein-protein interactions that have been shown to underlie a particular human disease. With the reduction in screening format from whole animal to cell to isolated protein, it is now possible to screen hundreds of thousands of compounds or extracts in a few weeks time using high-throughput screening (HTS) technologies. Here, a target protein is produced in large quantities by molecular biological means in a surrogate organism, placed in 96-, 384-, or even 1536-well plate formats, and compounds or extracts evaluated for inhibitory effects using robotics that work around the clock. It is hoped that screens of this design and scope will uncover new generations of pharmaceuticals that will have highly specific actions, targeting the underlying causes of disease, with very high potency, and leaving normal or undiseased cells untouched (Folmer *et al.*, 2010).

Unfortunately, this approach has not fully lived up to this expectation, and over the past 5 years, there is a growing recognition that cell-based screening systems have several advantages over these purely *in vitro* biochemical target screens. In cell-based screening, the compounds found active are necessarily active in a biological context, that is they are cell penetrant and stable to cellular enzymes, in addition to being efficacious at desired biochemical targets. As a result, the molecular leads found from cell-based screening are of higher quality and already have been selected for several desirable pharmaceutical properties (Appendino and Pollastro, 2010).

Examples from Marine Plants Illustrating Plant Sources of Drugs and Chemicals

Anticancer Agents from Marine Cyanophyta (Cyanobacteria)

The marine “plants” generally include a number of groups, including microscopic as well as macroscopic forms. The major subdivisions of the microscopic forms include dinoflagellates, cryptophytes, chrysophytes, cyanophyta (=cyanobacteria), and prochlorophyta. The major groups of macroscopic marine plants include the Rhodophyta (=red algae), Chlorophyta (=green algae), Phaeophyta (=brown algae), and a number of marine angiosperms (sea grasses); the latter represent terrestrial species that have “readapted” to life in the ocean. Although interesting and significant molecules have been isolated from all of these groups, secondary metabolites of special note have been obtained from marine cyanobacteria, dinoflagellates, and red and green macrophytes. Examples from these four groups follow below (Blunt *et al.*, 2010).

Curacin A and the “chemotype” concept

Cyanobacteria take on many different physical forms in the oceans, from gelatinous encrustations and tufts of 20 cm hairlike filaments, to microscopic unicells free in the water column. One species of pan-tropical distribution, *Lyngbya majuscula* (family Oscillatoriaceae), also known as “Mermaid’s Hair,” has been particularly plentiful in its production of structurally unique and biologically important secondary metabolites (Jones *et al.*, 2009). Such an example is given by a collection made in Curaçao, in the southern Caribbean, which was reported to possess an extract with fish, snail, brine shrimp, and cancer cell toxicity. Bioassay guided isolation efforts led to the isolation of several structurally unrelated substances which were each responsible for only some of the observed biological properties. The cancer cell and brine shrimp toxicity was principally due to a unique thiazoline-containing lipid, named curacin A (Figure 1). Its mechanism of cytotoxicity was shown to involve inhibition of microtubule formation, crippling the ability of cells to properly segregate chromosomes at mitosis. Several very valuable anticancer agents that are in common use in the clinic today work by this same essential mechanism (e.g., see Paclitaxel). Curacin A has been shown to interact with microtubules at the same site as the antigout drug, colchicine (an alkaloid from the plant *Colchicum autumnale* = autumn crocus). Unfortunately, curacin A was found difficult to work with *in vivo* because of solubility and stability problems. Recent synthetic medicinal chemistry efforts have overcome at least some of these

Figure 1 Structure of the antimitotic lipid “curacin A,” obtained from a Caribbean collection of the blue-green alga (cyanobacterium) *Lyngbya majuscula*.

problems, and work continues to develop an anticancer drug patterned on this “structural concept.”

Sources of curacin A for continued drug testing have largely been from materials freshly collected in Curaçao, although the living alga does produce curacin A in laboratory culture. Interestingly, when collections of *L. majuscula* were made from approximately 20 sites along the leeward coast of Curaçao, only two chemotypes, both quite limited in extent, were found to make curacin A. Continued investigations of this phenomenon have substantiated these findings, and thus a very intriguing conclusion must be drawn, which is of enormous significance to “biodiversity preservation.” It is widely held that in order to preserve the valuable genomic potential of a particular “species,” it is sufficient to preserve a few individuals or a limited population. This work with Curaçao collections of *L. majuscula* suggests that in order to accomplish the larger goal, it is actually necessary to consider preservation of the many, almost innumerable, “chemotypes” of a given species (Gerwick *et al.*, 2008).

Cryptophycin

Another very promising anticancer treatment derives from the freshwater cyanobacterium *Nostoc* sp. Although one of the active compounds, cryptophycin A, was first isolated as an antifungal substance, it was only after several more years that, on re-isolation, its anticancer potential was realized (Figure 2). In common with curacin A, cryptophycin also blocks microtubule assembly processes, although at a different drug-binding site (the vinca alkaloid site). In animal testing, cryptophycin has brought about actual “cures” of some tumor types. An enormous effort has been devoted to the total chemical synthesis of cryptophycin and several hundred analogs with the intent of ensuring that (1) a ready supply of the drug is available for clinical testing and (2) that advanced cancer treatment evaluations utilize the most effective molecule in this drug series. Testing of the drug in humans advanced to phase II trials, but was terminated due to lack of efficacy and toxicity. Sadly, it seems that possibly the wrong cryptophycin analog was taken forward into human clinical trial; however, there are continuing rumors that the drug class will be explored for its therapeutic utility by another major pharmaceutical company.

Toxins of Impact and Utility from Dinoflagellates

Dinoflagellates represent a very diverse group of organisms, made up of both freshwater and marine varieties. Dino-

flagellates are protists, which are not strictly considered plants or animals although they share characteristics of both, and appear to be the result of ancient tertiary endosymbiosis between animal cells, a unicellular red algal cell, and additional cell types. Some dinoflagellates are photosynthetic whereas others are parasitic to fish or to other protists. They can be very small or as big as 2 mm in diameter, such as in the case of *Noctiluca* sp. A curious feature of some dinoflagellates is that they are capable of bioluminescence.

Dinoflagellate blooms in the world's oceans have had tremendous impact on human society; despite this importance, many aspects of these organism's genetics, biology, and biochemistry are poorly understood. Hundreds of people suffer from the effects of seafood poisoning and millions of fish and other marine life are killed each year as a direct consequence of large blooms of dinoflagellates. Some of the coastal species can “bloom” during the warmer months and can even make the water appear red or golden colored; hence, the term “red tide.” For many years, seafood poisonings and fish kills have been associated with these dinoflagellate blooms, but it is only within the past decade that the chemistry behind these effects has been unraveled.

Ciguatoxin and maitotoxin

A prime example of a dinoflagellate toxin with huge impact on society is given by Ciguatera Seafood Poisoning (CSP), which is quite prevalent in tropical areas around the globe. CSP is more common than any other illness associated with consumption of tainted seafood. Generally, the poisoning results from ingestion of coral reef fish that have accumulated the toxins through their diet. Symptoms include, but are not limited to, memory loss, joint pain, miosis, erethism, cyanosis, and prostration. One of the more interesting symptoms associated with ciguatera is a neurological disturbance leading to reversal of hot and cold sensations. Most of the toxic effects of CSP are attributed to ciguatoxin, which is a metabolically oxidized derivative of a substance produced by the dinoflagellate, *Gambierdiscus toxicus*. The structure of ciguatoxin was deduced after a monumental 15-year effort by the laboratories of Dr Paul Scheuer at the University of Hawaii, USA, and Drs Takeshi Yasumoto and Michio Murata at Tohoku University, Japan (Figure 3). The structures of ciguatoxin and the probable precursor produced by the dinoflagellate are shown below as well. These compounds illustrate the common polyether motif found in many dinoflagellate toxins.

Another toxin that should be noted here is maitotoxin (Figure 4). Probably produced by dinoflagellates related to those that produce the ciguatoxin precursor, this compound is even more toxic than ciguatoxin. It is by far the largest compound ever isolated that is not a biopolymer (e.g., protein or carbohydrate). Its structure was also elucidated by the laboratories of Yasumoto and Murata, and represents a milestone in organic structure analysis.

Gymnodinium breve

For many years it was thought that seafood poisonings caused by dinoflagellates were limited to tropical regions of the world. However, in 1987, 14 dead humpbacked whales were discovered in Cape Cod Bay, Massachusetts, USA. Examination

Figure 2 Cyclic peptide structure of the anticancer metabolite “cryptophycin.”

Figure 3 Polyether structure of ciguatoxin, the active poison in ciguatera shellfish poisoning.

of the animals showed that they had been well until just before their deaths, appearing to be well nourished and showing no signs of ill health. A few months later, fishermen and beach-goers along the North Carolina coast began to complain of respiratory problems and eye irritation. Soon after, seafood consumers began to complain of diarrhea and dizziness. In later years and on a periodic basis, these same scenarios have been reported all along the east coast and the Gulf of Mexico. Most of these outbreaks have been connected with the dinoflagellate *Gymnodinium breve*. This dinoflagellate frequently forms large blooms, or "red tides," off the Florida coast, which result in many tons of dead finfish washing up on the beaches. This, in turn, repels many tourists and has forced many fisheries to be closed. In the early 1980s, the toxic constituents produced by this organism were found to be brevetoxin A and B, along with other structurally related compounds (Figure 5). Additionally, during especially heavy blooms and unfavorable weather patterns, the dinoflagellate brevetoxins are aerosolized and negatively affect pulmonary function in beachside populations, especially in the elderly. Red tide toxins have many and diverse consequences to human society.

Kainic Acid and Domoic Acid, Neurotoxic Anthelmintics from Red Algae

Two Japanese red algae, *Digenia simplex* and *Chondria armata*, have been employed for more than 1000 years in Japan for their potent anthelmintic properties; that is, eliminating intestinal worms, such as parasitic roundworms (*Ascaris lumbricoides*), whip worms (*Trichuris trichura*), and tape worms (*Tenia* spp.). Two closely related compounds, domoic acid and kainic acid (Figure 6), have been isolated from these red algae and are responsible for these therapeutic effects. These compounds were traditionally ingested by consumption of the producing algae, their names deriving from the Japanese names for these seaweeds, *domoi* and *kaininso*. Kainic acid has become an important tool in neurobiological research because of its potent neurotoxic effects on neurons, working through the glutamate receptor. However, domoic acid has been identified as the active poison in amnesic shellfish poisoning (ASP), which has recently struck both east and west coasts of North America. The levels of the drug that are ingested for anthelmintic properties are relatively small when compared with the amount of compound observed in the recent outbreaks of ASP. However, the macrophytic red algae were

determined to not be the culprit in the recent ASP outbreaks; rather, a planktonic pennate diatom, *Nitzschia pungens f. multiseries*, now renamed *Pseudonitzschia australis*, is the producer in this latter case.

The mechanism of action of these compounds is very similar, as is suggested by their closely related chemical structures. Both are analogs of glutamic acid, a well-known neurotransmitter found in the brain of mammals. The algae-derived substances are known as excitotoxic amino acids as they can mimic glutamate so as to cause massive calcium ion influxes into cells, a lethal event in various types of brain neurons. Domoic acid is two to three times more potent than kainic acid and 100 times more potent than L-glutamate at inducing these neurotoxic events. Although these compounds (domoic and kainic acid) are environmental neurotoxins to be avoided, they have shown considerable utility in biomedical research. For example, the resulting extensive neuronal loss seen with the appropriate dose of kainic acid is very similar to that observed for Huntington's disease, and hence, provides an excellent model for the study of this disease in humans. Kainic acid has also been used in the study of epilepsy and Alzheimer's disease.

A problem of epidemic proportion that occasionally arises from these excitotoxic amino acids is known as amnesic shellfish poisoning (ASP). It has been shown that blooms of the planktonic diatom *P. australis* result in a build-up of domoic acid in shellfish. Three highly publicized ASP outbreaks have occurred in the past 15 years in North America. The first was caused by the ingestion of mussels containing high levels of domoic acid from Prince Edward Island, Canada. The second was a large pelican kill in Monterey Bay, California. The domoic acid was found to accumulate through the food chain from diatoms to small fish to anchovies to pelicans. The last reported outbreak was in razor clams and Dungeness crabs in Oregon and Washington. The discovery of high concentrations of domoic acid led to the shutdown of these seafood harvests for several years, causing substantial economic hardship for afflicted communities. As a result of these ASP outbreaks, strict guidelines have been developed for the maximum allowed domoic acid content in harvested shellfish (20 ppm).

Green Algal Metabolites

Coral reef environments are habitats of high speciation and biodiversity ranging from microorganisms to top predators.

Maitotoxin

Figure 4 Structure of maitotoxin, the most complex nonpeptide structure ever determined.

Figure 5 Brevetoxin A, the causative fish poison produced by the red tide organism *Gymnodinium breve*.

Figure 6 Structures of the neurotoxic amino acid, glutamic acid, present in mammalian cells and two neurotoxic congeners, kainic acid from red algae, and domoic acid from red algae and diatoms.

Figure 7 Structure of the green algal predator defense compound halimedatrial and the “protoxin” halimatedetraacetate.

This biodiversity inherently creates intense competition between species, including predator–prey relationships such as between herbivores and their algal diets. Methods that algae use to protect against predation include calcification, production of tough spiny appendages, and the biosynthesis of chemically noxious deterrent molecules that are either toxic or deter feeding.

The green alga *Halimeda* sp. employs both calcification and chemical defense strategies. As a result, *Halimeda* species constitute the largest macroalgal biomass in many tropical reef systems. In feeding preference studies, and analyses of reef fish stomach contents, *Halimeda* spp. have been shown to not be a food source for generalist herbivores. Although calcification can provide algae with a strong structural protection against potential predators, some herbivores have coevolved specialized feeding structures that allow them to macerate even very tough materials. However, the dominance of *Halimeda* spp. in reef systems is enhanced through its production of a potent defensive and antifouling substance, a diterpenoid natural product named halimedatrial (Figure 7). Halimedatrial is a trialdehydic secondary metabolite that is structurally similar to the iridoid aldehydes and the insect antifeedant warburganal.

Halimedatrial displays a broad spectrum of activity against marine bacteria, a marine fungus, the division of fertilized sea urchin eggs, and the motility of sea urchin sperm. Halimedatrial was also toxic to common reef fish as well as being inhibitory of reef fish feeding at ecologically relevant doses (Paul *et al.*, 2007).

In the alga, halimedatrial exists in a “protoxin” form, a protected tetraacetate named halimatedetraacetate. Field experiments with *Halimeda* sp. have shown that halimatedetraacetate is converted to halimedatrial on wounding of the alga. This conversion is rapid and specific to the area of herbivory or wounding and does not take place simply on introduction to air but is an enzymatic conversion of a “protoxin” secondary metabolite to a highly potent antipredatory substance. This activated defense of *Halimeda* represents the first to be described in the marine environment. Interestingly, a similar activated defense system that produces feeding deterrents has previously been described in Russulacean mushrooms. Additionally, it has recently been shown that dialdehydes such as halimedatrial can crosslink proteins, and thus serve a dual function in coenocytic green algae (the entire thallus of *Halimeda*, like many other green algae, is constructed from a single

connected cell!). Specifically, on mechanical damage to the tissue, conversion of halimadatetraacetate to halimedatriol occurs, thereby cross-linking proteins and providing a clotting mechanism so that cellular contents are retained.

Examples from Terrestrial Plants Illustrating Plant Sources of Drugs and Chemicals

Anticancer Agents from Higher Plants

Paclitaxel

The story of the discovery and development of paclitaxel as an anticancer agent is a superb example of the opportunities and problems inherent in plant-derived medicines (Grothaus *et al.*, 2010). An NCI-sponsored plant collection program in the Pacific Northwest region in 1960 gathered 650 plant species for screening through various cell-based and *in vivo* anticancer evaluations. The twigs and bark of the Pacific Yew, *Taxus brevifolia*, showed very good activity in a cell assay and was subsequently subjected to bioassay-directed isolation of the active compound by Wall and Wani at the Research Triangle Institute. *Taxus* species have a rich history of use by native peoples for treatment of various illnesses, including cancer. Painsstaking efforts were involved in the isolation of the active component, paclitaxel, which was shown to be a new taxane derivative by X-ray crystallography (Figure 8). Despite its intriguing structure and impressive activity in cell assays (but not in antileukemic *in vivo* assays!), research on paclitaxel languished for nearly a decade due to a combination of short supply of the drug, difficulty in working with this lipid soluble substance, and lack of research funds.

Interest in the drug was rekindled when Susan Horwitz at the Albert Einstein Institute showed that paclitaxel had the opposite effect on microtubules compared with all other known classes of antimetabolic anticancer agents. By binding to a unique drug-binding site on the β -subunit of tubulin, paclitaxel promotes the stabilization of microtubules whereas other classes of antitubulin agents (e.g., vinca alkaloids, colchicines, and curacin A) promote their destabilization (Alfermann, 2010). This mechanistic difference fueled additional evaluations of paclitaxel, and once formulation problems were overcome, paclitaxel emerged as the most significant new anticancer drug of the past 25 years. Currently, paclitaxel has shown good efficacy to ovarian, breast, and lung cancers, as well as several others. However, its development was greatly impaired from severe supply shortages, a common issue for natural product-derived drugs. It has been estimated that it takes the recoverable paclitaxel content of four full grown

70-year-old trees to treat a patient for 1 year. At its peak, natural collections of 60,000 pounds of Pacific Yew bark were made in 1988 and 1989, which threatened the survival of this relatively common tree. Subsequently, supply of the drug was made plentiful by harvest of the needles from cultured trees (*Taxus baccata*), extraction of the essential core of the paclitaxel molecule, and its conversion by chemical synthesis into paclitaxel. More recently, plant cell culture techniques have been used to provide a steady and economical supply of paclitaxel (Alfermann, 2010). This latter process involves growing cells derived from *Taxus* in fermentation, followed by extraction and purification of the natural product. This fermentation process is attractive because the actual natural product is isolated, rather than an intermediate, thus eliminating most of the chemical reagents and solvents used in the semisynthetic approach. The 25-year development period from isolation to clinical use is typical of modern pharmaceutical development wherein many basic scientific, regulatory, and safety issues must be answered before drugs reach the market. The paclitaxel supply problem has subsequently initiated a national program to explore how to resupply a natural product drug in large scale during its development as an anticancer agent (Marasco and Schmidt-Dannert, 2007).

Camptothecin

The same group that discovered paclitaxel made a second major contribution in the fight against cancer. This latter compound, called camptothecin, comes from the wood and bark of the tree *Camptotheca acuminata*. Monroe Wall, who was working at the eastern regional Research laboratory of the USDA in Philadelphia, Pennsylvania, discovered it in the 1950s. Previously, this group had been screening plant extracts for steroids that could be used as cortisone precursors. In 1958, samples from this entire collection of extracts were sent to the NCI for testing against certain cancer cell lines. Only one extract, that from *C. acuminata*, showed activity in this particular biological assay (Gunatilaka, 2009).

Camptothecin was eventually isolated through the use of the Craig Countercurrent Distribution method, which takes advantage of different compounds having varying solubilities in nonmiscible solvents. In 1966, the structure of camptothecin and its corresponding sodium salt were published on the basis of a thorough spectroscopic and chemical degradation study (Figure 9). In early animal trials, camptothecin showed significant antileukemic activity to the L1210 cell line at concentrations as low as 0.2 mg kg^{-1} body weight of mice. By 1970, camptothecin had progressed to phase I clinical trials at NCI and soon progressed to phase II clinical trials.

Figure 8 Structure of the anticancer natural product “paclitaxel” from the tree *Taxus brevifolia*.

Figure 9 Structure of the anticancer natural product “camptothecin” from the tree *Camptotheca acuminata*.

Encouraged by these results, the NCI decided to introduce the water-soluble sodium salt of camptothecin into phase II clinical trials. The results of these trials were not very promising and camptothecin research lost much of the interest it had attracted in its earlier phase I trials. It was later discovered that the sodium salt of camptothecin was only one-tenth as active as the parent compound against the P388 cancer line.

In 1985, it was found that camptothecin kills cancer cells by a novel mechanism and interest was rekindled. These later studies showed that camptothecin and various water-soluble analogs worked by inhibiting the action of mammalian topoisomerase I (T-I, an enzyme in mammalian tissues responsible for unwinding DNA during the replication process) by a mechanism never before observed. This coincided with later discoveries that T-I is over-expressed in a variety of advanced cancerous tumors.

In 1991, two water-soluble analogs of camptothecin, topotecan and irinotecan, were introduced into advanced phase II clinical trials in the USA. Within the next few years topotecan was also approved for use in Japan and other analogs were approved for phase I clinical trials in Europe. Subsequently, topotecan and irinotecan were approved for use in certain types of ovarian and breast cancers in the USA.

Bioactive Alkaloids: Tropane Alkaloids

Alkaloids are a very diverse and abundant class of natural product. Their chemical structures range from relatively simple to very complex; but all contain one important theme, a basic nitrogen atom, usually heterocyclic, within their structural formula. Alkaloids are not only diverse in chemical structure, but are also diverse in the organisms that produce them. Alkaloids are categorized into different groups depending on the different moieties within their chemical structures. One of the best-known subclasses is the tropane alkaloids. The name is derived from the inclusion of a nitrogen-containing bicyclic appendage, tropane. Historically, two of the most important drugs in this class are atropine and cocaine (Figure 10). The tropane alkaloids continue to be vigorously investigated by many laboratories throughout the world.

Atropine was originally characterized from the poisonous plant *Atropa belladonna*. Aside from its poisonous properties when ingested, early usage of this plant involved placing the juice from the berry into the eye, causing dilation of the pupil. Women of the sixteenth century thought this to be a beauty-enhancing quality, hence the plant name "belladonna" ("beautiful lady" in Italian). In modern times, atropine has

been used to counteract the effects of cholinesterase inhibitors. These inhibitors, such as physostigmine and organophosphate insecticides, act as competitive inhibitors of acetylcholine at the muscarinic receptor. Numerous synthetic routes have been developed to produce atropine; however, none are economically feasible. At the present time, the most viable economic means by which to obtain this useful alkaloid is still by isolation from the raw plant material. Atropine can be isolated from a number of different plant sources (e.g., *Hyoscyamus muticus*).

Another tropane alkaloid, cocaine, was first isolated from *Truxillo coca* in 1860 with its intentional use in western medicine as an anesthetic. In Incan civilization this shrub was known as the "The Divine Plant." Natives would chew the leaves (mixed with lime so as to solubilize the alkaloidal substituents) in order to endure long journeys or extensive manual labor without experiencing the inherent fatigue associated with great exertion. In present-day times, cocaine's highly addictive stimulatory effect has given rise to many societal problems, in addition to retaining its importance as an anesthetic. Chemically, cocaine is a tropane alkaloid containing a methyl ester appendage. The primary mechanism of action of cocaine is that of a dopamine reuptake inhibitor. In essence, this leaves dopamine at the synapse for a longer time, giving rise to the euphoric sensation. Research on cocaine is still very actively pursued across the globe, from synthetic derivatives to effects on prenatal exposure to the drug.

Other Bioactive Classes: Steroidal Glycosides – Digitalis

Original therapeutic usage of *Digitalis* sp., commonly known as foxglove, can be found dating back to tenth century England, Wales, and Europe where it was used as an expectorant and treatment for epilepsy, swelling, and sore throats. Officially entering the London Pharmacopeia in the mid-1600s, and subsequently the pharmacopeia of most other countries by the eighteenth century, the late 1700s saw the emergence of *Digitalis* as a remedy for "dropsy." This disease condition is characterized by a swelling that results from inadequate heart function and is known today as congestive heart failure. The utility of this plant was introduced to Western medicine by William Withering in 1775, who was led to the medicinal value of *Digitalis* through conversations with a Welsh woman known for healing dropsy using herbal remedies containing foxglove. The active components of foxglove are classified as cardiac glycosides, two of which give rise to the drugs digoxin and digitoxin, the favored treatment for rapid atrial fibrillation (Figure 11).

Cardiac glycosides are naturally occurring steroids that are functionalized by sugar and lactone moieties. The most active of these possess an unsaturated lactone ring connected to C-17 of the steroid nucleus. Optimal cardiac activity also requires *cis* stereochemistry of the A/B and C/D ring junctures. Structure-activity studies on the cardiac glycosides have demonstrated that the sugar moiety aids in bioavailability and solubility, whereas functionalization of the steroid nucleus with hydroxyl, methyl, and lactone ring groups is essential for pharmacological activity. The unsubstituted aglycone, or steroidal portion, is less active than the glycoside (sugar attached).

Figure 10 Structures of the tropane alkaloids atropine and cocaine.

Figure 11 Structure of the cardiac glycoside digitoxin obtained from the foxglove *Digitalis* sp.

In treating heart failure, the cardiac glycosides of *Digitalis* function by increasing the strength and efficiency of ventricular contraction, thus shortening the length of contraction and allowing the heart muscle a longer relaxation time between contractions. This results in recovery of the myocardium, decreased heart rate, and improved renal function through enhanced circulation.

Nearly 30 different cardiac glycosides have been identified in *Digitalis purpurea* and more than 70 from *Digitalis lanata*. Cardiac glycosides have been observed in nine other *Digitalis* species. Interestingly, none of the major glycosides of *D. lanata* are identical to those isolated from *D. purpurea*, with the most common alteration in the molecule being acetylation of hydroxyl groups in the *D. lanata* representatives. This fact indicates great chemical, biochemical, and metabolic diversity among *Digitalis* species.

Historically, a drawback of *Digitalis* treatment is its toxicity. This toxicity led to its being eschewed by most medical practitioners until its reappearance in relatively modern treatments. The fact that no fewer than nine prescription products from *Digitalis* species are used to treat congestive heart failure, atrial fibrillation, and atrial and ventricular tachycardia demonstrates the human need and utilization of not only the innocuous plants, but also the noxious varieties, such as *Digitalis*. Moreover, the story of *Digitalis* may well have been the origin of the famous adage in the field of pharmacy, namely that – The difference between a poison and a medicine is simply a matter of dose.

Herbal Remedies

Ginseng

Perhaps the most venerable of traditional Chinese herbs is “ginseng” or “Korean ginseng,” also known by its Latin name *Panax ginseng*. Usage of *P. ginseng* has a long and rich history in China dating back to the Han dynasty some 2000 years ago. The earliest description of its application appeared in the oldest Chinese pharmacopoeia, believed to have been written in the first century during the late Han dynasty. It is the root of *P. ginseng* that is used extensively in Chinese medicine as an effective tonic for enhancing stamina as well as the capacity to endure fatigue and physical stress.

Panax ginseng was originally found in northeastern China, Korea, and eastern Siberia. Other congeners of ginseng, such

as the *Panax quinquefolius* (American ginseng) are also used widely as medicines. *Panax quinquefolius* was initially reported growing wild in the northeastern USA. Another common member is the Siberian ginseng (*Eleutherococcus senticosus*), which belongs to the Araliaceae family and contains distinctly different glycosides. The main source of *P. ginseng* used in the USA and Europe comes from Korea where it is cultivated extensively. Two main forms of ginseng are currently being used; white ginseng, which is processed from the air-dried roots of five to seven year old plants, and red ginseng, which is white ginseng that has been steam treated for 2–4 h.

Research on the chemistry of *P. ginseng* suggests that the major active components of the roots are the ginsenosides (glycosides), which are derivatives of the triterpene “dammarane.” To date, more than 20 ginsenosides have been reported from the roots, leaves, and flower buds of ginseng (Figure 12). Common sugars found attached to the protopanaxadiol core of these ginsenosides include glucose, maltose, fructose, and saccharose. In spite of the discoveries of these bioactive glycosides in ginseng, the precise pharmacological mechanisms of ginseng’s actions are unclear. However, there are extensive reports of the effects of ginseng on the function of the neuroendocrine system, the central nervous system (CNS; memory, learning, and behavior), carbohydrate and lipid metabolism, the immune system, and the cardiovascular system. For instance, ginsenoside Rb1 was demonstrated to have CNS-sedative, tranquilizing, and hypotensive actions whereas ginsenoside Rg1 was shown to be CNS-stimulating, hypertensive, and possess antifatigue properties. As this example demonstrates, many of the reports on the biological activities of ginseng’s metabolites are contradictory; this may be due to the difference of ginsenoside content in ginseng root or root extracts.

Echinacea

The application of *Echinacea* as a medicinal plant is derived from its use by Native North Americans. Traditional use of *Echinacea* involved the treatment of numerous conditions, such as external applications to wounds, burns, inflammation of lymph nodes (mumps), and insect bites. Internal uses of the plant included stomach cramps, headache, coughs, chills, measles, and gonorrhea. The root of *Echinacea* was the most important part of the plant used in these native treatments. There are also reports of the use of the juice or a paste of macerated fresh plant by Native North Americans. In view of

Figure 12 Two of a number of ginsenosides from *Panax ginseng*, a traditional herbal remedy from China.

Figure 13 Structure of cichoric acid, one of the biologically active components of *Echinacea*.

the multitude of beneficial uses of *Echinacea* by these people, it was likely one of their most important medicinal plants.

The first pharmacological studies on *Echinacea* extracts began in the early 1950s and were mainly concerned with its nonimmunological actions. However, we now know that *Echinacea* acts mainly *via* stimulation of the nonspecific immune system. The main immunostimulatory components of *Echinacea* extracts were found to be lipophilic alkylamides as well as cichoric acid, which is a derivative of caffeic acid. Cichoric acid (2,3-*O*-dicaffeoyltartaric acid) was first isolated from *Echinacea purpurea* and found to cause significant stimulation of phagocytotic activity in an *in vitro* granulocyte bioassay (Figure 13). In addition, polysaccharides have also been suggested to be active components in *Echinacea* juice and aqueous extracts. A purified mixture of polysaccharides from the roots of *E. purpurea* were found to increase *in vitro* phagocytosis by macrophages 23–32% at concentrations of 0.01 and 0.001 mg ml⁻¹. It appears that the complete immunostimulatory properties of *Echinacea* extracts are due to the combination of activities from several different classes of compounds.

Conclusions

The examples given here clearly demonstrate the pivotal role that plants have played in the development of much of our current pharmacopeia. Indeed, it has been estimated that as

much as 37% of all pharmaceutical sales are for compounds that derive, either wholly or in part, from natural products. For anticancer drugs, the percentage deriving from natural products is even higher (approximately 60%). Nevertheless, the enormous task that we require of pharmaceuticals, to have potent and selective action for a particular disease state, to be orally active and distribute with high efficiency to the target organ, and to be nontoxic to normal cells and tissues of the body, makes the development of any new pharmaceutical a long-term affair. On average, it is estimated that it requires nearly 15 years from the time of discovery to the time of clinical application of a new drug entity, a process estimated to cost approximately 1 billion US dollars in 2010.

Recognition of the enormous long-range value of plant-derived natural products, and the genetic sequences encoding for them, is one of the most compelling pragmatic arguments for biodiversity preservation. Indeed, the International Co-operative Biodiversity Group program in the USA has the simultaneous objectives of natural product drug discovery, biodiversity preservation, and developing short- and long-term economic benefit from ecologically preserved habitats, mainly in the tropics. Indeed, perhaps one of the strongest arguments in favor of protecting and promoting a rich biodiversity is provided by the direct socioeconomic benefit that is realized from plant species and their rich natural products chemistries.

As our understanding of the molecular basis for various diseases increases and defines new drug targets, we will need an ever-increasing source of molecular diversity to act as starting points for developing new generations of more potent and more selective drug agents. Nature's storehouse is still the largest and most chemically diverse source of unique molecular architectures. Preservation of this resource, and of the genes that encode for it, should be an overarching societal priority.

Glossary

Allee effect For population size to be regulated, they must exhibit negative density dependence. That is, the population growth rate must decline as the population gets larger.

However, under certain circumstances, some populations exhibit positive density dependence. This phenomenon, in which population growth rate increases as the population gets larger, is called an Allee effect. An Allee effect may generate a critical minimum population size, below which extinction will occur.

Angiosperm Flowering plants. A lineage characterized by flowers, seeds enclosed in carpels, specialized conducting elements in the phloem (sieve tube members) and xylem (vessels), presence of endosperm, double fertilization, and tectate pollen.

Diaspore A plant part distributed by dispersal, regardless of its developmental and morphological origins. A diaspore may be a naked seed, a seed enclosed in a fruit, or many seeds enclosed in a fruit. It may also mean bulbs or lengths of rhizomes. A good synonym is propagule.

Fitness Relative contribution of offspring to the next generation. An individual, genotype, or phenotype whose progeny constitutes a large proportion of the succeeding generation has high fitness.

Frugivores Animals that eat fleshy fruits.

Granivores Animals that eat seeds or achenes (grass fruits).

Herbivores Animals that eat plants. Usually excludes instances in which a single animal eats an entire plant, which is categorized as predation.

Phylogeny The evolutionary relationships among taxa (groups of related organisms), often portrayed with some kind of branching diagram, with branches representing speciation events. Typically, the true phylogeny of a group is hidden deep in the past, and evolutionary biologists must infer relationships statistically from DNA sequences and traits of modern organisms and, sometimes, traits of fossils.

Symbiosis Interaction in which two organisms live in close proximity. Symbiosis can be antagonistic or mutualistic. Often, the larger individual is called the *host*, and its inhabitant is called the *guest*.

Trophic level Position of a species in the food web (Figure 1). Plants – autotrophs which convert solar energy to chemical energy and utilize mineral nutrients – constitute the first trophic level. Primary consumers – animals that feed on living plants – constitute the second trophic level. The third trophic level is composed of secondary consumers – animals that feed on primary consumers. Predation, parasitism, grazing, and herbivory are intertrophic level interactions; competition occurs among species in the same trophic level.

Types of Interactions

Biotic interactions can be categorized by their effects on the interacting parties (Table 1). An interaction may not affect a species, or may be beneficial or detrimental. Antagonistic interactions negatively influence one or both species. Some interactions are clearly antagonistic: When a vole consumes an oak seedling, the rodent benefits whereas the plant dies. In other cases, it seems clear that both parties benefit, as when a hummingbird obtains nectar while transporting pollen from one plant to another. These interactions are termed mutualistic. The effects of other interactions may be more ambiguous. For example, Clark's nutcrackers not only consume pine-nuts but also disperse its seeds, and it is unclear whether the

interaction is mutually beneficial to both species or whether the birds benefit at a net expense to the tree. The fitness costs and benefits to the parties involved in such an interaction may also be conditional on the current environment. For example, during years of heavy seed production, birds may provide trees with a net benefit, whereas during poor seed years, the net effect of birds on the tree may be negative (Figure 1).

Ecologists seek to categorize interactions because they have distinct ecological and evolutionary implications. Within biotic communities, certain kinds of interactions increase species diversity whereas others reduce it. Similarly, the nature of interactions determines their impact on genetic diversity within populations.

Table 1 Pairwise ecological interactions between plants and animals, categorized by their effects on the fitness of each party

		Plant effect on animal	Animal effect on plant
Antagonisms	Herbivory	+	–/0
	Carnivory	–	+
Mutualisms		+	+

Antagonistic Interactions

Plant Consumers – Herbivores and Granivores

Types of Plant Consumers

Animals consume plants in all kinds of habitats, including marine, terrestrial, and freshwater, and do so in wildly diverse ways. For some plants, there is at least one animal species devoted to consuming each type of organ. Some animals

Figure 1 Trophic levels within a food web. Each trophic level is comprised of one or more species that consume individuals or resources at the next lower trophic level and are, in turn, consumed by species in the next higher trophic level. Arrows indicate the direction of flow of energy and resources in the food web.

remove tissues by chewing, others suck plant sap. Grazing individuals feed from many different individual plants. Some animals live within plants, literally surrounded by food. These include borers, gallers, and leaf miners.

Many animals chew on plants, just as we do. However, another important mode of consumption is to use straw-like mouthparts to pierce and suck fluids from vascular structures such as xylem and phloem saps, which transport water, minerals, and other compounds throughout the plant. Aphids are common sap feeders. Spider mites are another type of plant-sucking arthropod that may be familiar to unhappy owners of house plants. The origin of this feeding mode probably extends back to the Carboniferous with the Paleodictyopteroidea (Taylor and Scott, 1983; Labandeira, 1998), an assemblage of insects with sucking mouthparts.

Sap feeders share an interesting problem in common with many blood feeders: Neither blood nor plant sap provides a balanced or complete supply of vitamins and amino acids. One solution to this problem among aphids and their allies has been to host intracellular microbial symbionts with the enzymes necessary to convert common nonessential amino acids into essential rare ones, much as Midas converted base metals to gold (Douglas, 1994; Gündüz and Douglas, 2009). These intracellular guests inhabit special cells near the gut and oviducts and are transmitted by the mother to her eggs.

Perhaps the best-known mode of plant consumption is grazing. All of us are familiar with picturesque scenes of cows grazing or deer browsing in verdant pastures. Far from peaceful, these are scenes of graphic violence. Hundreds, perhaps thousands of plants are being eaten alive! Each grazer is eating photosynthetic organs from numerous living plant individuals. However, because the aboveground parts of most plants are

constructed of repeating, renewable modules called shoots, a single episode of grazing or browsing rarely kills a plant.

Less well-known grazers include parrot fish, which maintain well-mown lawns of algae on coral reefs. When portions of the reef are protected from parrot fish, luxuriant algal growth can smother the coral. Sea urchins graze kelp forests and, when their natural predators are eliminated, may create vast barrens on the ocean floor. On land, many plant-eating insects, such as grasshoppers, katydids, and some beetles, are grazers. Some grazers feed on roots. These include tiny soil insects called springtails, relatives of silverfish, which move around in the air spaces between soil particles, nibbling on roots. Microscopic crustaceans in the water column of oceans and freshwater lakes and ponds graze on tiny photosynthetic single-celled organisms called phytoplankton. In this case, however, the animals function more like predators because they must kill their prey to eat it.

In contrast to grazers, which move from plant to plant and eat only a portion of each plant, some animals feed on only one plant during their lifetime. In some cases, many generations of the consumer will occupy the same tree, evolving greater and greater adaptation to that one individual (Edmunds and Alstad, 1978). The problem can be especially acute for an isolated tree, because adaptive traits in its local pest population might not be diluted by maladapted immigrants from nearby trees (Tack and Roslin, 2010). An important unanswered question in evolutionary biology is how long-lived plants such as trees avoid being destroyed by rapidly evolving pests.

Some consumers live inside their food. Perhaps the most intriguing are gall-forming arthropods: wasps, flies, and mites that induce plants to form elaborate structures within which the animal munches away on the host. Galls occur in many forms, including small red swellings on leaf blades, large globular swellings on branches, or bristly structures in odd places. In most cases, the female insect induces the gall when she injects her eggs into the plant tissues. Her young hatch and feed inside the gall, where they are relatively protected from enemies and the rigors of the physical environment. The relative frequency of gall-forming herbivores increases with increasing aridity of the environment, presumably because insects in galls are less vulnerable to desiccation. Plant-feeding nematodes, called vinegar eels, often live in galls on roots. The earliest known gall was produced by an insect feeding on tree-fern fronds in the Carboniferous (Labandeira, 2006).

The same species of galling insect can produce very different-looking galls on different plant species, suggesting that the plant determines gall form. But, when the same host is attacked by different insects, very different-looking galls can be formed. Detailed work on the goldenrod ball gall indicates that both insect and plant genes interact to determine gall size (Abrahamson and Weis, 1997). Although gallers effectively manipulate plant development, which is a goal of many biotechnologists, little is known about the molecular mechanisms of this fascinating interaction (Shorthouse *et al.*, 2005). The complex structures of some galls have even led to the tantalizing hypothesis that viruses carried by the animal induce and direct gall development (Cornell, 1983).

Another group of consumers that lives inside plants are leaf miners. As their name suggests, the larvae of these flies and

moths burrow within a leaf like a miner, eating the tissue they excavate and leaving behind their waste material called frass. Because they must live between the top and bottom surfaces of leaves, leaf miner larvae are very flattened from top to bottom. Some leaf miners pupate within the mine; others exit the mine and pupate in the soil beneath the host plant. In addition to mining leaves, some other insects mine plant stems, burrowing just beneath the stem surface and leaving similar-looking feeding galleries.

Some miners snake along, leaving a long serpentine mine in their wake. Others scrape away at the sides of their chamber, creating a large blotch in the leaf. In many cases, miners can be identified to species from their mine appearance and host plant, which has also made them easy to detect in the fossil record (Labandeira *et al.*, 1994).

Bark beetles are economically very important plant consumers (Paine *et al.*, 1997). Adults attempt to bore into tree trunks, but healthy trees generally can “pitch” them out, literally flooding the bore holes with sap. However, the sap attracts more adults of these gregarious beetles and an ailing tree’s defenses can be quickly overcome. Female beetles then excavate extensive galleries just beneath the bark and lay their eggs in the termini of the tunnels. The larvae feed on both the host wood and on tree-feeding fungi that adult beetles transport to the tree in special structures called mycangia. Often, bark beetles do not kill their host but are indirectly responsible for its death because they introduce deadly fungal pathogens.

Evolutionary Responses of Plants

Plants have evolved numerous responses to their consumers. Primary among these is resistance. Plants resist consumers by defending themselves chemically or mechanically, or they may escape damage by being difficult for consumers to discover.

Chemical Defenses

Plants are highly proficient chemists. Early researchers were puzzled as to why plants produce such a startlingly diverse array of chemicals, which, because they had no known function in primary metabolism, became known as secondary compounds. Early theories proposed that these compounds were waste products from “pathological overproduction of carbon.” But this explanation begged the question, “Why so many ways of throwing out the trash?”

By the 1950s, phytochemists had begun speculating that secondary chemicals were important in plant defense, and this theory has dominated the latter half of the twentieth century. Nevertheless, competing hypotheses have held their own – notably that secondary chemicals are important in protecting plants from physical dangers such as ultraviolet light. Some plant chemicals do perform such functions, but it is certainly not clear why plants should have so many kinds of sun screen. Perhaps the most defensible alternative hypothesis is that secondary compounds are important in defense against microbial enemies such as fungal, bacterial, and viral pathogens. It is quite likely, in fact, that many compounds defend plants against both these enemies and animal consumers.

Chemical defenses are classified into three categories: digestibility reducers, toxins, and repellents. Many plants produce digestibility reducers such as tannins, which are large

molecular-weight carbon-rich compounds that bind proteins and make them difficult to digest. Thus, these compounds do not directly kill the consumer, but make the plant less nutritious to eat. This indirect mechanism of defense leads to important questions about the selection pressures that might have led to their evolution. In particular, it is not always clear that individual consumers know the nutritional value of their host. Moreover, in many cases the individual that chooses the plant is not the one destined to feed on it. For example, when choosing among a population of the same plant species, female butterflies do not necessarily lay their eggs on the individuals on which their larvae can develop best. Another question is, “If the chemical does not kill the consumer, why would it be evolutionarily advantageous to plants possessing it?” This question becomes even more vexing in light of considerable evidence that, when protected from other causes of mortality, consumers can compensate for poor food quality by consuming more (not less!) plant tissue. The leading hypothesis to explain this paradox is that consumers feeding on a plant with a digestibility-reducing compound will grow more slowly, making them more vulnerable to their enemies, such as predators, parasites, or diseases, and therefore die before consuming much plant tissue.

Toxins, as their name implies, are poisons that have direct negative effects on animals that consume them. Some plants are so toxic that apparently no animals will eat them. However, in many cases, certain animals have evolved mechanisms that detoxify extremely potent poisons. Often, these animals are specialists on that host plant. There may be strong evolutionary benefits to feeding on such a previously unexploited resource. The most obvious benefit is that no one else is using the plant, which reduces competition for food. However, because a toxic plant harbors so few consumers, it may also provide “enemy-free space” in which consumers are less likely to be discovered by predators or parasites (Bernays and Graham, 1988). Enemy-free space could also arise by a slightly different mechanism, which is nicely illustrated by small consumers on seaweeds. Small crustaceans called amphipods live on the algae they eat. Parrot fish also eat algae, but when they discover an amphipod, they snap it up like candy. Thus, amphipods that feed on very toxic species of algae are less likely to be consumed by herbivorous fish that are opportunistically omnivorous (Duffy and Hay, 1991).

Perhaps because of these kinds of benefits, many animals that have evolved the ability to consume a toxic plant have also evolved specialization to that host. For example, specialist herbivores may use the toxic compound as a cue to find their host. Additionally, the compounds may stimulate feeding or egg laying. This level of specialization sets up an important evolutionary trade-off for toxic plants. A compound that previously killed all consumers has become an attractant to at least one consumer. Individual plants that have higher levels of the compound may be better defended against most consumers but may be more attractive to the specialist. Conversely, plants with lower toxin concentrations will be less attractive to the specialist but may become vulnerable to other generalist consumers. This type of situation may create stabilizing selection and cause the plant population to evolve an intermediate concentration of the compound (Simms, 1992). Alternatively, the specialist could become a major cause of

death and seriously reduce abundance of the host. Indeed, when plants introduced into new habitats become noxious weeds, specialist consumers are sometimes imported to control them.

A final class of chemical defenses is repellents, which as their name suggests, repel animals from laying eggs on or eating plants that possess them. Some evolutionary biologists have argued that herbivores will not quickly evolve mechanisms that overcome repellents. This argument is based on the understanding that the rate of evolution depends partly on the strength of selection. Toxins impose strong selection for detoxification mechanisms because they kill animals. Repellents simply cause animals to look elsewhere for food, which might impose weaker selection. The strength of selection imposed by repellents on consumers will, however, depend critically on the fitness cost to the animal for finding an acceptable alternate host.

Animal uses of plant defensive compounds Whatever the evolutionary reasons for these compounds, plant secondary chemicals have enormous value to humans. For example, synthetic pyrethroids, which were originally extracted from a species of chrysanthemum, are valuable insecticides because they are effective but degrade quickly and so do not accumulate in the environment. Plant secondary chemicals are the source of virtually all of the herbs and spices that make food interesting to eat. In many cases, these compounds were first important in preserving foods and keeping them safe to eat. Finally, plant secondary compounds are an important source of pharmaceuticals (Farnsworth *et al.*, 1985; Harvey, 2008).

Other animals also use plant secondary compounds in interesting ways. Many consumers sequester plant compounds from their food and use them for their own defense; the best-known example being the monarch butterfly, which harbors cardiac glycosides from its milkweed hosts. Some animals even self-medicate with secondary compounds (Rodríguez and Wrangham, 1993). For example, healthy woolly bear caterpillars avoid poison hemlock, the plant used to execute Socrates. But woolly bears infested with a lethal parasitoid will preferentially consume poison hemlock (*Conium maculatum*), which can kill the parasite and allow the caterpillar to survive to adulthood (Karban and English-Loeb, 1997). European starlings protect their nestlings by lining their nests with fresh plant materials that inhibit mites from hatching (Clark and Mason, 1988). Animals may also use plant secondary compounds to preserve their food. Pikas, relatives of rabbits, live in burrows in talus slopes. To survive the winter in their alpine homes, they harvest and store enormous quantities of vegetation in haypiles. Pikas prefer to eat grass hay, but they often will add toxic herbs to haypiles, which reduces the chance of the pile becoming moldy (Dearing, 1997).

Mechanical Defenses

Mechanical resistance to consumers may be obvious, as in the case of spiny cacti and thorny shrubs, or more subtle, as in the case of silica bodies that wear down the teeth and mandibles of many consumers. Some plants combine both chemical and mechanical defenses. For example, Wright's datura (jimson weed) possesses both toxic alkaloids and leaf hairs called

trichomes (van Dam and Hare, 1998). It is generally supposed that mechanical defenses are more difficult for consumers to overcome (Coley, 1983).

When animals consume other animals, they eat tissue that has a composition similar to their own. However, plant tissues are generally richer in carbon and poorer in nitrogen than animal tissues. Partly because of mechanical defenses, a high proportion of the carbon in terrestrial plants is devoted to structural molecules such as cellulose and lignins. Animals lack the enzymes necessary to digest these compounds. Microbes do have such enzymes, however, and herbivores often have elaborate modifications of their guts which house microbial symbionts that can digest the fibrous fare.

Escape

In addition to defending tissues, plants may also escape consumers in time or space. Ephemeral plants, especially those with annual lifecycles, may obtain temporal escape with a lifecycle that does not sustain consumers long enough for them to complete their lifecycles. This constraint prevents the build-up of dense pest populations which short-lived consumers can attain on long-lived plants. Plants might also escape by appearing only during seasons when consumers are rare. For example, many cool-season plants are relatively unaffected by insect consumers, which are far more abundant during warm weather.

Highly dispersed plants may also escape consumption if the distances between them are greater than the average distance traveled by their consumers. This concept is embodied in the "resource-concentration hypothesis" (Root, 1973), which states that dense concentrations of host plants will harbor the highest densities of consumers. If a plant species is both short lived and rare, it may be difficult to find that it can complete its lifecycle before being found by consumers. This mechanism may in part be responsible for the astonishing diversity of certain tropical forests (Janzen, 1970; Connell, 1971), in which only one individual of each tree species will be found in a large area.

Finally, plants might escape herbivory when the enemies of herbivores are attracted to plant volatiles emitted from damaged tissues. Debate continues as to whether natural enemies of herbivores have evolved the ability to detect compounds passively emitted by damaged tissues or such volatile compounds are a plant adaptation that attracts "mobile body guards" (Dicke *et al.*, 1990), but these compounds are very promising as tools to reduce pest damage to crops.

Tolerance and Compensatory Growth

Even if plants are damaged by consumers, they may evolve mechanisms that allow them to maintain fitness in the face of damage (Simms and Triplett, 1994). Plants may tolerate damage through various compensatory mechanisms, including reallocating resources from undamaged plant parts to replace damaged tissues (Stowe *et al.*, 2000). Tolerance of consumers may be especially important among fast-growing plants living in resource-rich environments (Coley *et al.*, 1985).

Coevolution of Plants and Herbivores

Ehrlich and Raven (1964) conceived a coevolutionary hypothesis to explain the magnificent diversity of plant chemistry. They postulated that herbivorous insects cause plant mortality and that any novel trait that protected a plant from its herbivorous insects would quickly spread in the plant population. Further, they argued that escaping its herbivores would create for the plant the opportunity for a period of rapid speciation called an adaptive radiation. For the herbivores, newly evolved plant species represent unused resources. Any insect trait that allowed an insect to exploit these plants would likewise result in an adaptive radiation of herbivores. As Janzen (1980) later argued, the crucial characteristic of this process that distinguishes it from ordinary evolution by natural selection is its reciprocal nature. The plant evolves resistance to the herbivore; the herbivore then evolves a mechanism that negates the resistance, after which the plant evolves resistance to the herbivore, and so on, *ad infinitum*. With every crank of the coevolutionary process, new species arise through adaptive radiation.

This hypothesis has excited considerable controversy. Some authors argue that reciprocal coevolution is rare or non-existent because insect herbivores do not impose sufficiently strong selection pressures on plants (Jermy, 1976). Others argue that herbivores experience more selection from their natural enemies than from plants, and that moving to new plants is driven by the adaptive advantage of enemy-free space (Bernays and Graham, 1988). Further, Labandeira and Sepkoski (1993) pointed out fossil evidence that the great radiation of modern insects began 245 million years (My) ago and was not accelerated by the expansion of angiosperms during the Cretaceous period. However, neither insects nor plants have stopped evolving, and currently evolving systems provide the best tests of the coevolutionary hypothesis.

One way that scientists have tried to test the coevolutionary hypothesis is to compare the evolutionary lineages (phylogenies) of host plants and insect consumers that narrowly specialize on that group of hosts. Coevolution can lead to a pattern called cospeciation (Brooks, 1979), in which the two phylogenies match, much like fingers do when the palms are placed together. One hand represents the plant lineages, the other the insects. At the base of the palm is the ancestral species; the fingers represent various derivative lineages. An alternative phylogenetic pattern, in which lineages do not match, is produced by host switching. Host switching is the phenomenon whereby specialist consumers shift host species and then speciate on that new species, without any speciation by the host plant.

The alliance of Hawaiian silverswords and the plant hoppers that live and feed on them provide a particularly exciting pair of phylogenies to test the coevolutionary hypothesis. The Hawaiian silverswords are derived from a pair of ancestral species in the rather prosaic group of California plants called the tarweeds (Baldwin, 1997). Over the past 5 My, the Hawaiian descendents have rapidly radiated into a stunningly diverse array of species. Some of these Hawaiian descendents are magnificent rosette plants with life histories much like century plants – they live long lives terminating in the production of giant flowering stalks. Others are multibranched perennial shrubs. Most are attacked by members of the plant

hopper genus, *Nesosydne*, in the family Delphacidae. The plant hoppers are highly host specific; each species feeds on one or a few closely related plant species (Roderick, 1997). Phylogenetic analysis of molecular data from the plant hoppers and their hosts reveals a pattern of cospeciation: Each plant hopper species is most likely to use the host species that is most closely related to the host of its closest relative. This pattern is exciting, because it is expected to arise from reciprocal coevolution.

However, other mechanisms could produce the same pattern. For example, the plants could be evolving in response to some other selective pressure, with the insects following along behind. Matching phylogenies can also arise when both an insect and its host plant speciate simultaneously in response to some external event as, for example, when they become geographically isolated from their main populations by a geologic event such as mountain building (Roderick, 1997). Thus, phylogenetic comparisons alone cannot deduce whether coevolution has occurred. Other types of data must be examined. Careful observation of host used across hybrid zones suggests that the most likely explanation of the match between silversword and plant hopper phylogenies is that plant hosts are speciating in response to some external pressure and plant hoppers are tagging along behind plant host speciation (Roderick, 1997).

Community and Ecosystem Effects of Plant–Consumer Interactions

Considerable evidence suggests that consumers can reduce the fitness of individual plants and thereby impose selection pressures that produce evolutionary changes in plant traits. However, it is less clear whether consumers influence plant abundance in the landscape. This issue is at the heart of a controversy that has raged among community ecologists for decades regarding the relative importance to community structure of top-down control by consumers of their resource populations (e.g., Hairston *et al.*, 1960) versus bottom-up control of consumer populations by resources at the base of the food web (e.g., Lindeman, 1942). The current view is that both types of forces interact in complex ways to structure biotic communities (e.g., Oksanen *et al.*, 1981). However, several competing hypotheses aim to explain how these forces interact. Three of the major models are summarized here.

Donor control models predict that while plants feed their consumers, the latter have little effect on plant abundance. Thus, biomass of organisms at one trophic level is a function of the productivity of their resource base at lower trophic levels. This means that adding resources to the base of a food web will trickle up the web, increasing biomass at all trophic levels. In contrast, consumer control models predict that each trophic level can be controlled by either its resources or its consumers, but not by both. They further predict that the direction in which the control moves depends on the trophic level being examined and the number of trophic levels in the ecosystem. In particular, plants, at the base of the food web, are expected to dominate in ecosystems with odd numbers of trophic levels, whereas herbivores will dominate in ecosystems with even numbers of trophic levels. Thus, increasing abundance in a particular trophic level will cascade up and down the food web, alternately expanding or shrinking trophic levels. Finally, keystone predation models predict that the

species composition at each trophic level modifies the relative effects of resources and consumers.

The last model is more complex than the previous two, incorporating aspects of each. It is of particular interest here because it incorporates information about the relative vulnerability to consumers (i.e., resistance) of different resource (e.g., plant) species. The keystone model predicts that species diversity in resource populations can be maintained if resource species exhibit trade-offs between their relative competitive abilities and their relative resistance to consumers (Paine, 1966). Further, the model predicts that when resources are scarce, consumer populations will be small, the plant community will be dominated by a few fast-growing, strong competitors that are highly vulnerable to consumers, and is therefore consumer controlled. Under nutrient-rich conditions, consumer populations will be large and the plant community will consist primarily of a few slow-growing, well-defended species that are resource controlled because of their heavy investment in resistance. At intermediate levels of nutrient availability, both types of plants can coexist because of the trade-off between competitive ability and resistance to consumption (Leibold *et al.*, 1997). Consequently, species diversity will be greatest at intermediate levels of productivity (Grover, 1994; Holt *et al.*, 1994; Grover, 1995; Leibold, 1996). Other factors will determine whether these diverse communities are controlled by consumers (top-down) or by resources (bottom-up).

Leibold (1999) examined this prediction in planktonic communities of fishless ponds that varied in their level of mineral nutrient availability. These communities consist of photosynthetic planktonic algae (phytoplankton; single-celled green plants) that are grazed by herbivorous microarthropod zooplankton. Leibold found that algae in low-nutrient ponds consisted primarily of small, unprotected forms thought to be fast-growing but susceptible to grazing. Algae from more eutrophic (nutrient-rich) ponds were larger and often sheathed or gelatinous forms thought to be slow-growing but resistant to grazers.

In another analysis, Chase *et al.* (2000) reviewed studies of temperate terrestrial grasslands to determine whether the effects of consumers on plant biomass fit the keystone herbivore model, which predicts that consumer control should be strongest at high levels of resource availability and decline with declining productivity. They reviewed the results of experiments that manipulated the presence or absence of large grazers. Because most temperate grasslands are water-limited, they sought evidence for a correlation between consumer effect and precipitation. As predicted, the proportional effect of consumers on plant biomass declined significantly with increasing precipitation. Schmitz (1994, 1997) found a similar relationship between plant productivity and the effect of insect herbivores on plant biomass. Further, Chase and colleagues found a turnover in species composition among plants along the precipitation gradient, as predicted by the keystone model.

Plants as Consumers – Carnivorous Plants

The most ubiquitous interaction between plants and animals is the use of plants by animals as sources of material resources

and energy. However, there are a few plants that turn the tables. In a world of plant-eating animals, carnivorous plants eat animals (Givnish, 1989). More than 500 species in nine plant families have evolved the carnivorous habit.

Mechanisms of Prey Capture

Carnivorous plants capture prey in several remarkable ways (Table 2). The evolutionarily independent origin of carnivory is demonstrated by the many ontogenetic origins of the traps. A pitfall trap is a tubular structure, often containing liquid, which prey can enter but have difficulty leaving. Five different plant families capture prey in some kind of pitfall trap, called tanks or pitchers, and these traps may be comprised of leaf

Table 2 Presence (+) or absence (–) of adaptations for active prey attraction, capture, and digestion in carnivorous plant genera and species

In: Abrahamson WG (ed.) *Plant-Animal Interactions*, pp. 243–290. New York: McGraw-Hill.

rosettes (e.g., *Brocchinia*), modified leaves (e.g., *Sarracenia*), or modified leaf-tips (e.g., *Nepenthes*). Some plants have active mechanisms to trap prey. For example, the leaves of the Venus flytrap (*Dionea muscipula*) function like a miniature steel-jawed trap when tripped by the hapless prey. There are even aquatic plants (e.g., *Utricularia*) with sophisticated underwater traps that slurp up prey unlucky enough to trip them.

Costs of Carnivory

Carnivorous plants are usually restricted to sunny, moist, nutrient-poor habitats, such as bogs and fens. Their slow growth and restricted distribution suggests that there are fitness costs associated with carnivory. For example, it has been argued that leaves morphologically specialized for prey capture have compromised photosynthetic abilities, making carnivorous plants poor competitors. This hypothesis is supported by studies of the pitcher plant *Sarracenia alata*, which produces two kinds of leaves, a “regular” leaf and one that is modified into a pitcher. The plant responds to competition from neighboring vegetation by diverting resource allocation from pitchers to regular leaves (Brewer, 1999a, b). Small stature and slow growth also make many carnivorous plants (e.g., *Pinguicula* and *Utricularia*) vulnerable to being buried by litter fall (Brewer, 1998, 1999a, b). Because of their compromised competitive ability, carnivorous plants generally respond poorly to addition of nutrients to their habitat, being easily outcompeted by plants that thrive under richer conditions. This characteristic creates important conservation concerns in many parts of the world where atmospheric input of anthropogenic nitrogen is significantly increasing nitrogen availability in previously nitrogen-poor bogs and fens.

Another fitness cost of carnivory was identified by Zamora (1999), who found that *Pinguicula vallisneriifolia* tends to trap its own pollinators. He also found that reproduction in the plant is limited by pollen availability, indicating that feeding on its pollinators reduces plant fitness.

Benefits of Carnivory

As with so many plant novelties, plant carnivory was noticed by the inquiring mind of Darwin (1875), pp. 1–2, who demonstrated that the sticky traps of *Drosera rotundifolia* do indeed capture and digest animals. Darwin’s son, Francis Darwin (1877b), first demonstrated experimentally that prey capture enhances the growth and reproduction of this species. Similar studies have subsequently found that in most circumstances, carnivorous plant growth benefits from prey capture.

In many cases, the majority of a carnivorous plant’s nitrogen and phosphorous is obtained from prey, but only a small proportion of other necessary nutrients come from prey. Experiments suggest that plant growth is generally restricted by the rate of prey capture; plants could utilize many more prey than they were able to catch. Carnivorous plants tend to be frugal with their nutrients, practicing particularly efficient internal recycling of nitrogen and phosphorous.

Many elegant methods have been used to examine in more detail nutrient uptake from prey in carnivorous plants (Adamec, 1997). In particular, putatively carnivorous plants can be offered insects reared on media enriched in the stable nitrogen isotope N^{15} . If the plant tissues subsequently become N^{15} enriched, this indicates that their nitrogen supply has been supplemented by insect proteins. Using this method, Hanslin and Karlsson (1996) found that *D. rotundifolia* and several species of *Pinguicula* in a subarctic environment took up 29–41% of the nitrogen available in insect prey they were offered. Further, root uptake of nitrogen was stimulated by prey capture, an unanticipated additional benefit of carnivory. Experiments performed in glasshouse or laboratory environments generally reveal even greater uptake efficiencies.

Carnivorous plants show interesting developmental changes during maturation of their carnivorous organs. Using fluorescent dye tracers, Owen *et al.* (1999) found developmentally regulated bidirectional transport by leaf glands in the pitcher vine, *Nepenthes alata*. In mature leaves, the glands transport fluids directly from the pitcher fluid to the plant vasculature (internal plumbing system), apparently functioning in nutrient uptake. However, in immature closed leaves, the glands secrete fluid from the vascular tissues into the pitcher, building up a supply of fluid in which to eventually trap prey. Expression of hydrolase, an enzyme involved in prey digestion, commenced when the pitcher first opened on maturity, increased for several days, and would largely cease after 2 weeks without prey (Gallie and Chang, 1997). However, adding prey-derived resources such as amino acids to the pitcher fluid could induce hydrolase expression in pitchers that had ceased expression due to lack of prey.

Nonprey Guests – Iniquiline Communities

Prey-digesting guests (iniquilines) are very common in pitfall traps, and their bodily wastes provide for some carnivorous plants the sole means of benefiting from prey. The foodwebs of iniquilines in pitcher plant (*Sarracenia* spp.) traps have been the subject of numerous highly informative community and population ecology studies.

In one of the most arcane modes of nutrient uptake, *Roridula gorgonias* hosts a bug, *Pameridea roridulae*, that feeds on insects trapped on its sticky leaves. Although the plant has no known method of digesting its prey, stable isotope studies indicate that it acquires N^{15} label from prey. It apparently derives nutritional benefit via exudations from the bug guest which has dined on the labeled prey (Ellis and Midgley, 1996; Midgley and Stock, 1998). This example, however, highlights the vulnerability of insectivorous plants to kleptoparasites (animals that steal prey). Spiders, in particular, frequently compete with carnivorous plants for prey that have been attracted to the plant.

Mutualistic Interactions

In addition to antagonistic interactions in which one party feeds on the other, plants and animals may also interact in ways that can benefit both parties. Far from being pleasant

affairs, however, mutualistic associations can be highly vulnerable to cheating, which often makes them evolutionarily uneasy truces between parties. The delicate evolutionary and ecological balances that can be achieved by these organisms are truly fascinating and lead to some common evolutionary issues.

One important question regards the degree of specialization between mutualists. Specialization is useful because it allows the evolutionary development of elaborate lock-and-key mechanisms that exclude cheaters and maintain the mutualism. However, specialization is an evolutionarily vulnerable position, because extinction of one partner species can spell doom for the other. Further, in mutualistic interactions that must be reconstituted each generation, which is the case for all animal-plant interactions, specialization might make it more difficult for individuals to find the correct partner.

Plant-Protecting Ants and Plant-Feeding Ants

As described previously, plants have evolved a variety of mechanisms that defend them against herbivores. One of the strangest defenses, though, is provided when plants are guarded by ants. Once thought to be rare and unusual, myrmecophytes (ant plants) are actually widespread and ecologically important. In many cases, these relationships appear to be quite casual. Visiting ants may rob nectar from flowers, but perform some guarding services in return. However, the term myrmecophyte is generally reserved for the more specialized case in which an ant colony resides in special structures provided by the plant.

Benefits to Ants – Costs to Plants

Tropical myrmecophytes display the most sophisticated development of this type of interaction. In the neotropical regions alone, associations between ants and myrmecophytes have been described for about 250 plant species from 19 families, and up to 180 ant species from five subfamilies (Davidson and McKey, 1993). These ant plants may provide ant housing in specially modified stems, hollow thorns, or specialized leaf pouches called leaf-domatia. The trees or shrubs often feed ants with amino acid- or sugar-based solutions produced by extrafloral nectaries. The most developed myrmecophytes may also provide food in the form of specialized structures composed of lipids (Beccarian bodies), proteins (Beltian bodies), glycogen (Müllerian bodies), or some combination. In the most elaborate cases, plants may provide everything – room, board, and drink – to their ants.

Food provision for ants may be quite costly to myrmecophytes and studies show that plants regulate production of food structures. Removing Müllerian bodies from Central American *Cecropia* (Moraceae) trees stimulates their production. In contrast, when Müllerian bodies accumulate, which would happen if ants were not present, plants cease production (Folgarait *et al.*, 1994).

Many ant-plant interactions have an important third partner through which the ants obtain benefit: sap-sucking homopterans tended by ants. Ants derive benefit from these homopterans in two ways. They may keep “milk herds” from which they obtain honeydew, or they may be in the “beef

business” and eat the homopterans they tend. Rather than simply supporting ants, the plants in these situations must also support homopteran consumers. Homopterans increase plant risks too, as they are often important vectors of plant diseases.

The homopteran mode of ant benefit provides few options for control by the plant. This problem is illustrated with the African myrmecophyte *Leonardoxa africana*, on which the same ant species (*Aphomyrmex afer*) may tend one or both of two different homopteran species. Gaume *et al.* (1998) found that homopteran identity influenced the costs and benefits to the plant of ant patrol. One homopteran, the pseudococcid, could support larger colonies of ants, leading to better plant defense. This homopteran was also more efficient at producing ant biomass; ants tending pseudococcids did not use other plant resources. Moreover, the plant could directly control pseudococcid colony size by regulating domatia volume. Plants that provided a smaller total volume of the swollen stems used as domatia supported fewer pseudococcids and therefore fewer ants. However, when ants tended coccids, the other homopteran, they also used plant resources from the extrafloral nectaries. Thus, when ants tended coccids, the only control that plants had over homopteran feeding was indirectly through nectary production. Plants that produced fewer nectaries supported fewer ants, and fewer ants could tend fewer coccids.

Benefits to Plants – What Motivates Ants to Patrol?

Ants have frequently been observed killing and removing insect herbivores, and numerous experiments demonstrate the efficacy of this defense. Fonseca (1994) observed more than four times as many herbivores on *Tachigali myrmecophila* plants from which he removed *Pseudomyrmex concolor* ants as on plants with intact ant colonies. Further, the daily rate of herbivory was about 10 times lower when ants were present, resulting in experimental plants without ants exhibiting about twice as much cumulative herbivore damage during the 18-month experiment. Leaf longevity was also substantially higher on plants with ants. It is interesting to note that these ants do not eat the herbivores they kill. Instead, they feed exclusively on catenococcid insects they tend inside the domatium, which is the hollow rachis of the compound leaf.

Ants are also effective deterrents of mammalian herbivory. For example, the African myrmecophyte, *Acacia drepanolobium*, possesses two kinds of thorns. The swollen thorns are domatia in which *Crematogaster* ants live and rear their broods. The unswollen thorns slow plant damage by browsing mammals, but browsers may compensate by feeding longer. Ants provided far more effective defenses (Stapley, 1998). When a browsing mammal was encountered and stung by ants, it stopped feeding immediately and could not be induced to feed further on that tree.

A second benefit that patrolling ants may provide is in competition with neighboring plants. Ants will prune vines (lianas) and branches of neighboring trees, effectively preventing their host tree from being overgrown (Janzen, 1966). The result of this vigilance is that the host tree might occupy a dramatically open cylinder of space amid otherwise densely packed tree canopies. Although such pruning of neighbors clearly benefits the host tree, it also benefits the ant colony by

reducing the number of directions from which it may be attacked by competing or predatory ants (Davidson *et al.*, 1988).

However, ants sometimes harm their own host by pruning it rather than its neighbors. For example, *Crematogaster nigriceps* so severely prunes its host tree, *A. drepanolobium*, that the tree cannot flower and is sterilized (Stanton *et al.*, 1999). In the habitat studied, four species of ants compete strongly for hosts, and *C. nigriceps* fares poorly in the violent conflicts over nest space. Instead of pruning neighboring trees, *C. nigriceps* prunes its own tree, apparently because it cannot prune neighboring trees occupied by competitively dominant ants. Indeed, careful observation of a large number of trees occupied by *C. nigriceps* revealed that these trees were always pruned in such a way as to avoid canopy contact with adjacent trees occupied by competing ant colonies. Canopy pruning of its own tree appears to be a defensive response by a *C. nigriceps* colony to competition with dominant ants which prevent it from pruning their trees.

Ants Feeding Plants – Myrmecotrophy

Finally, a very different group of plants receives nutrients from the ants they house. These plants are also known as ant epiphytes. Epiphytes are plants that live on, but derive no nutritional benefit from, the branches of other plants. Myrmecotrophic epiphytes provide ant domatia in hollow or inflated roots, hollow rhizomes, or folded leaves. Ants then act as “mobile roots,” gathering food items for the nest, processing them, and then depositing the resulting waste and fecal matter within the plant. The best studied of these systems is *Myrmecodia tuberosa* (Rubiaceae), an epiphytic shrub of southeastern Asia and northern Australia. This species also has elaiosome-bearing seeds, a typical feature of ant-dispersed seeds. The ants feed on these food bodies and then “plant” the seeds along the walkways they create in the canopies of the trees their plant “homes” inhabit.

Plant-Pollinator Interactions

An important and obvious characteristic of plants is that, with few exceptions, they are rooted to the ground and cannot move. This poses a crucial problem for sexual reproduction: Immobile mates must exchange gametes, meaning that pollen must be moved to the ovule. Pollen can move passively with fluid flow in the physical environment. Wind pollination has been successful among the gymnosperms and water pollination is found among many aquatic angiosperms. However, as many allergy sufferers know too well, most of the pollen produced by wind-pollinated plants never reaches its intended target. Many land plants avoid this inefficiency by using animals as pollen vectors. Most temperate angiosperms and almost all tropical angiosperms are animal pollinated.

Of course, animals do not move pollen around as a favor to the plant. Attracting pollen vectors has been an important evolutionary problem for plants and the need to attract pollinators has probably been a primary driver in the evolution of flower morphology. Animal-pollinated flowers often have large, brightly colored structures that function as “advertising” for the goodies available to the visitor. The rewards may be nectar, other more specialized chemicals, or even the pollen

itself. As with any purveyor of treats, the flower also must contend with thieves. For example, nectar-robbing bees may drill through the flower wall and gain access to the nectar without transporting pollen (Inouye, 1980). Other visitors may obtain rewards yet be too small to trip the elaborate pollen-application mechanisms of some flowers (Bertin, 1989).

The potential for cheating selects for specificity in pollinator attraction. Specificity can also promote pollinator fidelity. Simply attracting a pollinator once is not sufficient. To ensure fatherhood, the plant must attract an animal that will visit other flowers of the same species. Moreover, to avoid inbreeding, the recipient flower must be on a different individual. These competing needs create strong evolutionary pressure for plant traits that promote pollinator specificity. As might be expected when sex is involved, response to this selection pressure has led many plants and animal pollinators to exhibit fascinating and baroque relationships (Darwin, 1877a, b, 1984; Grant and Grant, 1965). For example, male euglossine bees depend on flowers of plants in the euphorb and orchid families for fragrances which they use as pheromones to attract mates (Williams and Whitten, 1983; Armbruster, 1993). In another instance, male insects are tricked by orchids into thinking that they have found a mate, when in fact all they have discovered is a cleverly shaped and scented mimic (Peakall and Beattie, 1996).

Role of Plant Pollinators in Plant Diversification

An important aspect of these highly specialized relationships is that they can sometimes prevent mating between genetically compatible individuals, a phenomenon known as reproductive isolation. Evolution in a trait that promotes reproductive isolation can quickly lead to speciation. Traits that create the opportunity for rapid speciation by exploiting novel resources such as new pollinators are considered “key innovations.”

Identifying such key innovations is a sticky problem in evolutionary biology. Circularity arises because the characteristic that best defines a group, and therefore allows it to be identified as speciose (having lots of species), is frequently also the character postulated to be the key innovation responsible for the radiation. One way out of this thicket is to identify a causal link between the putative key innovation and one of the processes that determines diversity.

Floral Nectar Spurs as a Key Innovation

One especially persuasive example of a key innovation is floral nectar spurs. These structures are critically involved in pollinator specialization because they hold nectar deep within the flower and make it available to only a narrow range of floral visitors. Animals must either be small enough to enter the spur or have sufficiently long and narrow mouthparts to sip nectar from the spur. Observing the 12-inch long nectaries of a Madagascar orchid, *Angraecum sesquipedale*, prompted Charles Darwin (1877a, 1984, pp. 162–163) to predict correctly the existence of a moth with a sufficiently long proboscis to pollinate this fantastic flower. Nectar spurs have evolved independently in several distantly related families and genera of flowering plants and, as would be expected were spurs driving diversification, spurred groups significantly have

more species than closely related groups without spurs (Hodges, 1997).

Experimental research has corroborated the putative link between nectar spur morphology and pollinator fidelity. Within two groups of orchids, experimental manipulation of spur length significantly changed rates of both pollinia (pollen bags) removal by pollinators and fruit set (Nilsson, 1988; Johnson and Steiner, 1997), demonstrating that spur morphology directly influences pollinator-mediated reproductive success. In a study of columbines, hybrids varied in floral characters, including spur length and orientation, and these morphologies differentially attracted either hummingbirds (primary pollinators of *Aquilegia formosa*) or hawk moths (primary pollinators of *Aquilegia pubescens*), and thereby promoted reproductive isolation (Hodges and Arnold, 1994). However, the presence of a hybrid zone indicates that floral morphology has not prevented pollination “mistakes.” Nevertheless, comparative analysis suggests that North American columbines have, over the past 2 My, radiated into species that are primarily bee, hummingbird, or hawkmoth pollinated and have corresponding floral morphologies (Whittall and Hodges, 2007).

Insect Pollination in the Fossil Record and the Angiosperm Radiation

The role of plant-pollinator interactions in reproductive isolation has also led to the much grander hypothesis that insect pollination was a “key innovation” leading to the co-radiation of flowering plants (Angiosperms) and anthophilous insects (the groups most involved in pollination), including certain bees and wasps (Hymenoptera), various families of flies (Diptera), and butterflies and moths (Lepidoptera).

One necessary prediction of the insect-pollination Angiosperm-radiation hypothesis is concurrent diversification of the angiosperms and anthophilous insects. Despite recent progress in our understanding of flower evolution (Specht and Bartlett, 2009; Endress, 2011), controversy still surrounds the dates of angiosperm diversification (Crepet, 2008). Nevertheless, recent analysis of the land plant record has produced a richer story that even more powerfully supports a tight evolutionary relationship between plants and pollinators (Labandeira and Sepkoski, 1993; Crepet, 2008). Indeed, insect pollination seems to have preceded the origin of angiosperms and insect diversity may have waxed, waned, and resurged with the fortunes of different plant groups.

Fossil plant and insect morphology suggests that many ancient gymnosperms, cycads, and early seed plants from the Middle Jurassic and Early Cretaceous were pollinated by insects with body parts specialized to obtain pollen, nectar, or other plant rewards (Labandeira, 2010). However, the global turnover from gymnosperm to angiosperm floras in the early Cretaceous apparently extirpated much of this diverse plant-pollinator biota and reduced insect diversity for 20 My until the subsequent diversification of angiosperm flowers and pollinators.

The earliest angiosperms tended to have bowl-shaped, open flowers accessible to a variety of small unspecialized insects (Friis *et al.*, 1987). These would not have facilitated reproductive isolation. After another 45 My, as angiosperms began to dominate the flora, reproductive isolating

mechanisms became evident. The fossil record of this time suggests pollinator specialization, including the earliest fossil evidence of bees and other long-proboscid insects, and floral traits such as tube-shaped flowers, which restrict floral rewards to specialized pollinators (Crepet, 2008). Molecular and fossil data also suggest the concomitant rise of new angiosperm groups characterized by rapid diversification of lineages with specialized pollinator associations (Lavin *et al.*, 2005).

Pollination Syndromes

Many plant species that share animal pollen vectors also share similar suites of floral traits, such as color, shape, symmetry, and scent, which appear to attract those kinds of animals. For example, hummingbirds fly by day, have excellent color vision, possess long beaks, and visit flowers while in flight. Correspondingly, hummingbird-pollinated flowers are day-blooming and tend to be brightly colored, often red, bilaterally symmetrical and tubular in shape, and frequently pendant. Floral traits also may correspond to the physiological needs of pollinators, as with hummingbird-pollinated flowers, which tend to produce copious sucrose-rich nectar that helps fuel the notoriously high metabolic rates of their pollinators. A number of these trait combinations, which are called pollination syndromes, are summarized in Table 3 (Howe and Westley, 1988).

Implicit in the concept of pollination syndromes is the assumption that floral evolution has been strongly entrained by interactions with specific classes of pollinators, leading to strong specialization. Specialization, however, may be an evolutionary dead end. A plant highly specialized and dependent on one or a few species of pollinator is seriously vulnerable to extinction of its pollinators. Dependence on specialized pollinators can also lead to “Allee effects,” which arise when populations become too sparse to persist. For example, individuals in small, isolated populations of the annual plant farewell-to-spring (*Clarkia coccinea*) were visited by so few pollinators that they could not produce enough seeds to replace themselves (Groom, 1998). If individual reproductive rates dip below replacement levels for very long, a population can dwindle to extinction.

Figs may provide a particularly impressive example of this problem. Fig trees are ecologically important components of tropical forests because the fruits they produce support frugivorous animals that are important seed dispersers for many other forest plants. Figs do not have large showy flowers to attract pollinators. Instead, fig reproduction is exquisitely dependent on minute wasps that pollinate small flowers held tightly inside the closed fig. The wasp’s end of the bargain is met when the eggs it lays inside the fig hatch and its larvae feed on a few of the many developing seeds. Individual fig trees flower for a relatively short time but fig wasp populations cycle constantly. Maintenance of the wasp population requires that female wasps emerging from a mature fig find and lay eggs in figs of other trees of the same species that are flowering at times other than their natal tree. Genetic evidence shows that, despite their minute size and short lifespan, these wasps routinely move pollen between trees 5–14 km apart (Nason *et al.*, 1998). This interdependence argues that viable fig populations may require a higher density of trees than is generally assumed necessary for plants not involved in such

Table 3 Pollination syndromes: putative characteristics of flowers associated with particular groups of pollinators

<i>Animal</i>	<i>Opening time</i>	<i>Color</i>	<i>Flower Odor</i>	<i>Shape</i>	<i>Symmetry</i>	<i>Nectar</i>
Entomophilous						
Beetles	Day/night	Dull or white	Fruity or aminoid	Flat or bowl-shaped	Radial	Often absent
Carion or dung flies	Day/night	Brownish or greenish	Fetid	Flat or deep; often traps	Radial	Rich in amino acids, if present
Bee flies	Day/night	Variable	Variable	Moderately deep	Radial	Hexose-rich
Bees	Day/night	Variable, but not pure red	Sweet	Flat or broad tube	Radial or bilateral	Sucrose-rich for long-tongued bees; hexose-rich for short-tongued bees
Hawk moths	Night	White or pale green	Sweet	Deep, often with spur	Radial	Ample and sucrose-rich
Butterflies	Day/night	Variable; often pink	Sweet	Deep or with spur	Radial	Often sucrose-rich
Vertebrate-pollinated						
Bats	Night	Drab, pale; often green	Musty	Flat “shaving brush” or deep tube; often on branch or trunk; hanging; abundant pollen	Radial	Ample and hexose-rich
Birds	Day	Vivid; often red	None	Tube; often hanging	Radial or bilateral	Ample and sucrose-rich

a tight mutualism (Anstett *et al.*, 1997). The only study to test this contention, however, found that despite heavy forest fragmentation by humans, banyan trees (a type of fig population on the Cook Islands) have not yet suffered from Allee effects (Compton and McCormack, 1999).

Plants can sometimes escape the grips of their pollinator addiction. In one group of Hawaiian shrubs, species derived from insect-pollinated ancestors have evolved wind pollination, apparently by passing through a transitional stage characterized by a relatively generalized pollination system (Weller *et al.*, 1998).

Several researchers have questioned the assumption that most plant–pollinator relationships are highly specific (Jordanano, 1987; Waser *et al.*, 1996). Even specialization in insect pollinators is usually defined at the level of plant genus or family, not species. Further, insect species confined to one plant species in one geographical area often visit other plant species in other parts of their range (Thompson, 1994). In fact, specialization by pollinators may be largely a function of which plants are available. Short-lived insects might appear to be specialized, because they visit only one or a few plant species with which they temporally co-occur, whereas social insects, which have long-lived colonies and thus the opportunity to overlap with many plant species, often exhibit serial specialization on a large variety of plant species. For example, the only bee species on the Galapagos Islands is colonial and has been recorded visiting flowers of at least 60 plant species in 28 families. Finally, clustering of flowers into certain categories thought to be canalized through selection by pollinators may actually reflect physiological or morphological

constraints in plants. For example, Chittka *et al.* (1992) argued that clustering of flower colors into particular narrow ranges may be a function of the physical and chemical constraints imposed by plant pigments rather than constraints imposed by the vision systems of different pollinators. If these arguments are true, the pollinator syndrome concept may be clouding our thinking about and study of plant–pollinator interactions. Researchers may be oblivious to, or fail to record, flower visitation by the “wrong” pollinators (Waser *et al.*, 1996; Ollerton *et al.*, 2009).

Competition for Pollinators

Pollinators are an important resource that plants may compete over. Whether plants compete for pollinators is determined by the factors that limit seed production. In many situations, plant reproduction is limited by mineral resources and plants are unable to increase fruit set with increased pollinator availability. However, there are many examples of plants in which reproduction is limited by pollinator availability. Pollinator limitation has important implications for plant conservation. For example, prolific flowering by invading plant species may negatively impact native plant communities by depriving native species of pollination (Grabas and Laverty, 1999; Takakura *et al.*, 2009).

Fruit and Seed Dispersal: Childhood Mobility in Plants

Many plants depend on animal dispersal of seeds and fruits (diaspores). Unlike pollen dispersal, in which insects are

major players, diaspore dispersal is dominated by vertebrates. Dispersal is important because a plant often cannot develop successfully in the shade of its mother. Dispersal may also be an important mechanism by which progeny escape the predator or pathogen populations that are well adapted to exploit them, having built up on and become adapted to their parents (Augsburger and Kelly, 1984; Mangan *et al.*, 2010). Finally, dispersal allows plants to colonize newly opened habitat.

Types of Dispersers

Vertebrates

Fish Perhaps the most unexpected and amazing diaspore dispersers are fish. This phenomenon has been most extensively studied along the Amazon River (Kubitzki and Ziburski, 1994). However, it is likely to be important in many areas with extensive seasonal flooding (e.g., Horn, 1997). Floodplain plants with heavy fruits or seeds embedded within hard shells might require dispersal by fish. Catfish are effective dispersers whereas characins are destructive and act largely as predators of all but the smallest seeds.

Mammals Many mammals are important seed-dispersal agents. Primates and bats are the most important mammalian dispersers in tropical areas. Both types of animals can move quickly across the landscape, thereby dispersing diaspores to long distances. Diaspore dispersal by bats is particularly important for forest regeneration after land abandonment in the Neotropics (Parrotta *et al.*, 1997; Medellin and Gaona, 1999). In temperate regions, diaspores may be dispersed by ungulates (e.g., antelopes, elephants, and zebras) and by many supposed carnivores. For example, black bears consume prodigious quantities of fruit, sometimes competing with humans for delectable berries (McCloskey, 1948).

Birds and Reptiles The earliest known examples of animal dispersed plant propagules include the fleshy seeds of cycad progenitors, which might have been consumed by ancient reptiles (Burbidge and Whelan, 1982), although more data are needed to support this conjecture (Butler *et al.*, 2010; Manchester *et al.*, 2010). Many dinosaurs were certainly important fruit and seed eaters and may have functioned as dispersal agents. Their modern descendants, the birds, are arguably the most important class of fruit and seed dispersers today. Otherwise, modern reptiles are only rarely important diaspore dispersers.

Birds can be hard on seeds. Beaks may break up the seed coat, rendering the embryo vulnerable to digestive acids and enzymes. Seeds may be ground up in the gizzard. However, the guts of frugivorous birds tend to be short and gentle (Levey and Del Rio, 2001) and many seeds require a trip through a bird's digestive tract to germinate successfully (Samuels and Levey, 2005; Traveset *et al.*, 2008).

Although large numbers of a broad range of birds feed on fruits, few depend solely on fruits (Izhaki and Safriel, 1989). Even waxwings, perhaps the most specialized frugivores in the temperate region, also feed on insects when they are available. Nevertheless, fruits are an important resource with which many birds produce body fat prior to migration (Bairlein and

Gwinner, 1994). Moreover, in the tropics, where seasonal constraints on fruit production may be weaker, several groups of birds depend almost exclusively on fruits (e.g., quetzals, toucans, and barbets).

Invertebrates

Ants The only major insect seed dispersers are ants. Myrmecorous seeds, those adapted to ant dispersal, often possess a starch- or lipid-rich body called an elaiosome attached to a tough and smooth seed coat that is difficult for ants to crack. Seed size is constrained by selection by ants – large ants tend to carry larger seeds than small ants.

In comparison with vertebrates, ants do not carry seeds very far (Kalisz *et al.*, 1999), but they can be important dispersers for many plants. Ants may either store seeds in the nest or remove the elaiosome and then discard seeds at the nest entrance or colony waste-pile (Servigne and Detrain; Beattie and Culver, 1982). Both locations tend to have well-aerated, nutrient-rich soil that can improve plant growth. Seeds collected by ants may also gain some protection from other seed predators, which generally avoid active ant nests (Heithaus, 1981).

An important conservation issue in many areas has been the loss of native seed-collecting ants to competition from invading ants. Argentine ants (*Linepithema humile*), which have invaded Mediterranean climates globally, collect fewer seeds than the native ants they outcompete, and are predicted to cause changes in plant diversity and ecosystem function (Rodríguez-Cabal *et al.*, 2009). In other situations, introduced ants seem to function as effective seed dispersers (Stuble *et al.*, 2010). However, they sometimes produce subtle differences. For example, invading fire ants (*Solenopsis invicta*) introduced into the Southeastern USA collect seeds of bloodroot (*Sanguinaria canadensis*) but alter the distance and direction that seeds are dispersed (Ness, 2004).

Other insects Occasionally seeds are dispersed by insects other than ants. For example, scarab beetles may bury seeds with dung (D'Hondt *et al.*, 2008). Grassland termites might also aid in dispersal of grass seeds (Vigni and Melati, 1999).

Plant Adaptations to Diaspore Dispersers

Dispersal syndromes Animal dispersers impose selection on fruit and seed characters and biologists have described "dispersal syndromes," suites of characters that appear to be shared among propagules sharing certain groups of animal dispersers or particular modes of transportation (Table 4). For example, most dog owners can describe the common characteristics of propagules dispersed on animal fur and feathers, which include barbs, hooks, and barbed hairs that cause these annoying passengers to attach firmly to socks as well as fur. However, as with pollination syndromes, controversy rages over whether these suites of traits result from selection by particular groups of animal species or instead reflect evolutionary constraints imposed by the morphology and physiology of plant ancestors (Jordano, 1987).

Plant Adaptations to Frugivores

A ripe fleshy fruit both attracts and rewards a potential seed disperser. During ripening, fruits often change color, from an

Table 4 Characteristics of fruits and seeds dispersed by different animals

<i>Animal</i>	<i>Color</i>	<i>Fruit Odor</i>	<i>Form</i>	<i>Reward</i>
Vertebrate dispersers				
Hoarding mammals	Brown	Weak or aromatic	Indehiscent thick-walled nuts	Seed itself
Hoarding birds	Green or brown	None	Rounded seeds or nuts	Seed itself
Arboreal mammals	Yellow, white, green, or brown	Aromatic	Arillate seeds or drupes; often compound and dehiscent	Pulp protein, sugar, or starch
Bats	Pale yellow or green	Musky	Various; often hanging	Pulp lipid- or starch-rich
Terrestrial mammals	Often green or brown	None	Indehiscent nuts, pods, or capsules	Pulp lipid- or starch-rich
Highly frugivorous birds	Black, blue, red, green, or purple	None	Large drupes or arillate seeds; often dehiscent; seeds > 10 mm long	Pulp lipid- or starch-rich
Partly frugivorous birds	Black, blue, red, orange, or white	None	Small or medium-sized drupes, arillate seeds, or berries; seeds < 10 mm long	Pulp often sugar- or starch-rich
Feathers or fur	Undistinguished	None	Barbs, hooks, or sticky hairs	None
Insect dispersers				
Ants	Undistinguished	None to humans	Elaiosome on seed coat; seed < 3 mm long	Oil or starch elaiosome with chemical attractant

inconspicuous green that is poorly discernible amid the foliage to a contrasting color such as red, blue, yellow, or black, which is conspicuous to visually searching frugivores with color vision. Fruit color may reflect the types of animals being attracted, which suggests that a disperser's visual system imposes selection on fruit color. For example, primate-dispersed fruits tend to contrast with surrounding foliage less than do bird-dispersed fruits (Lomascolo and Schaefer, 2010).

The ripe fruit may contain various nutritious goodies that attract prospective dispersers, including sugars, minerals, water, lipids, and proteins. These resources can be costly for plants to provide, and some plants produce fruits or seeds that mimic more nutritious fruits but are much less nutritious than their model fruits. A plant might get away with this strategy, particularly if it produces large numbers of fruits, but animals with a choice generally choose the most nutritious fruits (Schaefer *et al.*, 2003).

An important problem for the plant is to ensure survival of at least some of its seeds. The fruit must remain on the plant long enough for the seed to develop and be provisioned by the mother. Unripe fruits often contain toxins and palatability-inhibiting compounds (Stiles, 1989). Perhaps for some readers the most memorable example of this phenomenon will be the inadvertent bite into an unripe persimmon.

However, even ripe fruits must be protected from pathogens and predators. How to selectively protect the fruit? The chili pepper plant has an ingenious method. It produces capsaicin, which deters fungal pathogens and mammals, both of which destroy seeds, but has no effect on bird dispersers, which lack capsaicin receptors and hence do not experience chilies as "hot" (Tewksbury and Nabhan, 2001).

Occupying an attractive and nutritious fruit, seeds must possess traits that promote survival during fruit consumption and digestion. Sometimes seeds can be easily separated from the pulp and are discarded by frugivores prior to digestion (remember watermelon seed spitting contests). Some seeds require passage through a vertebrate gut before they will germinate (Traveset, 1998). Such seeds are relatively indigestible,

due to either hard seed coats, toxins, or simply the incompetence of the frugivore gut, and pass through unharmed. Fruits may also contain chemicals that manipulate the animal's behavior or gut activity (Izhaki, 2002). A fast ride through the gut reduces the opportunity for digestive breakdown of the seed, but too rapid passage could land the seed right under the maternal plant.

Frugivores vary in where and how they deposit seeds. Those that discard seeds as they are eating often deposit seeds individually, but may also fail to move seeds any distance from the parent. Dispersers that regurgitate seeds may move them further and often deposit seeds individually. When seeds are defecated, however, they may be concentrated at high densities. Such dense concentrations of seeds may attract seed predators or secondary seed dispersers. Ants, for example, often remove seeds from dung piles (Levey and Byrne, 1993). If no secondary dispersal process spreads these seeds, they may germinate under extremely competitive growing conditions.

Frugivores function as seed dispersers only if they move away from the parent plant before defecating, regurgitating, or otherwise discarding the seed. Some fruit compounds sensitively manipulate the guts of dispersers in ways that might maximize or optimize dispersal distances. For example, glycoalkaloids of solanum fruits induce constipation in birds, function as laxatives in mammals, and deter seed predators (Izhaki, 2002). Mild toxins might also improve dispersal by deterring foraging frugivores from finishing all the fruits at a bonanza tree. Specialization on particular fruits is rare among frugivores, perhaps because no one species of fruit provides a complete diet. This, too, may be a mechanism that benefits plants because it encourages frugivores to move about to achieve a complete diet (Wahaj *et al.*, 1998).

Seed Predators as Dispersers

Many diaspores lack a fleshy fruit or other enticement to attract frugivores. These seeds may nonetheless benefit from dispersal by their predators. Many rodent and bird seed

predators hoard seeds for future use. When they forget or lose buried seeds, they may be quite effective dispersal agents. Many members of the crow and jay family are important seed hoarders and dispersers. For example, Clark's nutcrackers carry pinon pine seeds up to 22 km (Vanderwall and Balda, 1977) and bury them in small clumps (scatter-hoards). Behavioral studies indicate that these birds are highly effective at finding hoarded seeds, and will even dig into a meter of snow to find known hoards. However, individual birds will commonly store more than twice as many seeds as needed, perhaps to protect themselves against theft. Theft may be common, especially among social seed predators, such as pinyon jays. Pinyon jays can find and exploit hoards that they observed other birds burying (Bednekoff and Balda, 1996).

Caching may have significant effects on the local ecosystem. Clark's Nutcracker initiates forest succession after large fires by moving in limber pine seeds from long distances (Coop and Schoettle, 2009). These birds can also influence the genetic structure of tree populations (Rogers *et al.*, 1999).

Seeds dispersed by predators sometimes have interesting adaptations that promote offspring survival. Oaks, for example, are dispersed by their seed predators, which include birds and rodents. Both types of animals crack open acorns and feed on the cotyledons of the embryo. During germination, the embryo root (radical) emerges from the apical (pointy) end of the acorn. Several studies by Steele *et al.* (1993) have discovered that digestibility-reducing astringent tannins are concentrated at the apical end of the acorn. Further, all acorn consumers studied, including insects, birds, and rodents, preferentially consume the basal (cap) end of the acorn, which leaves the embryo intact and viable. Partially eaten acorns can germinate, sometimes at higher rates than those of intact acorns.

Evolutionary Dead Ends?

As with other forms of specialized dependence, specialization to a particular propagule disperser can be an evolutionary dead end. Perhaps the most famous example involves the fruits of the *Calvaria major* tree on the island of Mauritius in the Indian Ocean. This tree had not been observed to recruit young seedlings for more than 300 years when Temple (1977) surmised that it was lacking its essential fruit disperser, which was the dodo, a large flightless pigeon that had gone extinct in the late 1600s. Temple was able to mimic dodo digestion by feeding the *Calvaria* seeds to turkeys.

Turkeys were not available to rescue *Calvaria* on Mauritius, but Janzen (1981) has argued that another tree has survived the loss of its dispersal agent in Central America through such a substitution. Huge, rare guanacaste (*Enterolobium cyclocarpum*) trees in Costa Rica produce fruits that are readily eaten by domesticated horses and cattle. Janzen speculated that these fruits were once dispersed by the Pleistocene horse (*Equus fratermus*), which went extinct in the New World some 10,000 years ago. He demonstrated that most seeds pass unharmed through the guts of domesticated horses, and went on to argue that these animals, which were introduced by Spanish conquistadors 500 years ago, have replaced the lost dispersal agent. Thus, adaptation to one seed dispersal agent preadapted the fruit to other similar agents.

Summary

Plant-animal interactions are ubiquitous and important. A common theme throughout the study of plant-animal interactions is the enormous effect that these interactions have on plant and animal evolution. There is strong evidence that the interaction between plants and insect pollinators is the primary driver of diversity in flowering plants and the groups of insects most involved in pollination. Selection by animal consumers has driven the evolution of numerous plant defense traits. These traits form the basis of many of the uses that we make of plants today. Plant-based fibers, pharmaceuticals, and flavorings all derive from plant evolutionary responses to consumers. The plant fitness trade-offs between these defensive traits and competitive ability also play an important role in determining the composition of biotic communities.

The primary benefit that plants obtain from animals is mobility. Many, perhaps most, plants depend on animals to transport pollen and propagules. In many cases, the interactions between plants and their animal transportation providers are highly specialized and mutually beneficial. These specialized mutualisms can be quite vulnerable to extinction of either party, which is an important issue in both plant and animal conservation.

Finally, plant photosynthesis converts solar energy into chemical energy and thereby provides the energetic basis for most of the world's terrestrial life. Plants are therefore the foundation of the global terrestrial ecosystem. Aside from the decomposition of plant litter through the microbial food chain, this energy flows into the global ecosystem via animal consumers of plants. Understanding how plant-animal interactions influence this process is crucial to understanding how intact ecosystems provide the goods and services on which human endeavor, and indeed all life, depends.

Plant–Soil Interactions

Joan G Ehrenfeld[†], Rutgers University, NJ, USA

Glossary

Aerenchyma Porous root tissue, especially well developed in wetland plants, that allows diffusive flux of oxygen from above-ground tissues to root tips. This tissue supports the respiratory demand of the root tissues and allows oxygen to leak into the surrounding soil.

Mycorrhizae A root tip that is infected with fungi in a mutually beneficial partnership. The fungal hyphae explore large volumes of bulk soil, absorbing nutrients, and transferring them to the plant; the plant supplies the organic carbon necessary for growth and energy production to the fungus. Different groups of fungi form vesicular–arbuscular mycorrhizae (fungal hyphae invaginate into the plant root cells) and ectomycorrhizae (fungal hyphae grow between plant root cells and form a thick sheath over the root tip, but they do not invaginate). Several other forms are specific to particular plant families (Ericaceae, Orchidaceae).

Net mineralization/immobilization The net result of microbial decomposition of organic matter is either the incorporation of nutrient elements (particularly nitrogen) into the microbial biomass, rendering it unavailable for plant uptake (immobilization), or their release into the soil solution (mineralization) after microbial demand for each element has been satisfied.

Nutrient uptake capacity The instantaneous rate of nutrient acquisition, usually measured in brief (1–2 h) incubations. Uptake capacity reflects the abundance of transport sites on the root cell membranes and their affinity for nutrient ions.

Plasticity Ability of a plant to respond to temporal changes or spatial variation in environmental conditions by altering the size or the distribution of plant parts. These are phenotypic, rather than genetic changes.

Rhizodeposition The mixture of sloughed cells, mucilages, and low-molecular-weight sugars, amino acids, and other compounds leaked from root cells, which are

deposited in the soil adjacent to the surface of fine roots. Exudation takes place from the root tip back to the zone of suberization. The chemical quality and quantity of the exudate is altered by the presence of mycorrhizae.

Rhizosphere Volume of soil adjacent to, and strongly influenced by a plant root. The rhizosphere is usually considered to extend about 2 mm from the root surface, and includes the “rhizoplane,” or soil directly in contact with the root surface.

Siderophore Chemicals secreted by roots (primarily non-protein-forming amino acids), which complex with insoluble metal ions bringing them into solution and permitting their transport to and uptake into the root.

Soil aggregate A crumb-sized unit of soil, composed of aggregated soil minerals, microbes, and soil microfauna, which are cemented together by a combination of biological materials such as polysaccharide secretions, fungal hyphae, and chemical substances such as precipitated carbonates or silicates. Aggregates are classified by size and stability in water (disintegrating versus retaining their structure and integrity).

Soil organic matter Organic substances, including a wide variety of carbohydrates, proteins, lipids, waxes, phenolic, and humic compounds, which accumulate in soil as a result of both plant and microbial growth. These compounds include low-molecular-weight materials, which are rapidly decomposed to carbon dioxide; larger compounds, which may be slowly decomposed over years to decades; and large, complex, aromatic substances, which may be stable within the soil for millennia. Soil organic matter affects all aspects of the soil's biology, chemistry, and physics.

Soil texture The relative abundance of sand ($50\ \mu\text{m} < \phi < 2\ \text{mm}$), silt ($2\ \mu\text{m} < \phi < 50\ \mu\text{m}$), and clay ($\phi < 0.2\ \mu\text{m}$) particles in the soil (USDA criteria). Particle size distribution determines the distribution of pore sizes, which in turn strongly affects the behavior of water in the soil.

Introduction

Plants are often assumed to be passive recipients of the environmental conditions that happen to exist at the location in which they grow. Soils supply mineral nutrients, and water, and they provide anchorage, but they also set limits on plant growth. Plants, however, provide the organic substrate that forms the basis for all biological activity in the soil and that forms the soil organic matter; their growth drives the formation of soil from bedrock and alters its chemistry and physics. This chapter reviews the two-way street that

constitutes the plant–soil system and examines the implications of these mutual effects for the management and conservation of biodiversity.

Soil–plant interactions take place over a wide range of spatial and temporal scales (Figure 1). At a scale of microns, roots etch microscopic channels of weathering within mineral grains and provide a variety of different habitats for microbial growth. These microscale phenomena cause millimeter-scale differences in the abundance and diversity of microbes and the soil micro- and mesofauna. Nutrients flow toward roots over distances of millimeters to centimeters; active uptake causes sharp concentration gradients of nutrient elements, moisture, and acidity. These modifications spread out from the root surface to form a cylinder of differentiated, rhizosphere

[†]Deceased.

Figure 1 Concept of three-dimensional structure of plant-soil interactions. Processes occurring across dimensions of time (minutes to millennia) and space (microns to hundreds of kilometers) occur with respect to the species pool – both the numbers of species and the kinds of species.

soil that may be millimeters thick. Mycorrhizal hyphae extend from the root surface into the soil over distances from centimeters to meters; they bind soil particles together into aggregates and contribute to the long-term accumulation of soil organic matter. The quantity and quality of such millimeter-scale effects vary among plant species, and so patches of soil filled by roots of different species may become chemically and physically different at scales of centimeters to tens of meters, depending on plant size. These species-level effects may translate into stand-level effects. At these larger spatial scales, however, local and regional differentiation of soils due to differences in topography, geological substrate, and geological history may override the effects of plant species and constrain the nature of the plant-soil interactions. But at these scales, plant communities also exert control over the long-term accumulation of organic matter.

Plant-soil interactions occur over an equally great range of temporal scales. At the level of the individual plants, uptake of nutrients and water occurs more or less continuously over

hours, but rates vary over seconds or minutes, depending on environmental conditions. The aggregate effects of this uptake over periods of months (seasons) or years reflects the continuity of plant community composition. Similarly, the exudation of substances used by the microbiota, and the response in microbial growth and metabolic activity, occurs over timescales of minutes to hours, but the aggregate effect on soil properties and on plant growth extend over seasons and years. Over the long term (decades to centuries or millennia), different plant communities cause different types of soil to develop.

Finally, these patterns of interaction themselves depend on the size and diversity of the available pool of plant species. In highly diverse communities, the effects of individual species may be masked by the variability among those effects, or by the overlapping nature of root and shoot systems. In communities that are species-poor, either because of human manipulation (e.g., forest plantations of a single species) or because of biogeographic and climatic constraints (e.g., boreal

forests with few species), the individual species-specific effects seen at small scales may translate into effects seen over hectares or square kilometers.

Within each of the temporal and spatial scales of interaction, the mechanisms creating the interaction are subjected to feedback, both positive and negative (Figure 2). Indeed, the presence of feedback in the soil–plant system is one of its salient properties: The results of a particular mechanistic effect alters the environment so as to modify (increase or decrease) the continued activity of that mechanism. Feedbacks have been recognized as crucial in mediating such disparate processes as the supply of mineral nutrients through decomposition, and the activities of soil pathogens and mycorrhizae.

The complex interplay of soil and plants has commanded attention for a long time. Gilbert White, in *“The Natural History of Selbourne”* in 1778, observed that *“In a district so diversified with such a variety of hill and dale, aspects, and soils, it is no wonder that great choice of plants should be found.”* Darwin pointed out that plant growth is modified by the presence of soil fauna, especially earthworms; he noted that Gilbert White had also observed this a century earlier. The German scientist Justus Liebig (1876) founded the scientific basis for agriculture by emphasizing the role of soil in controlling vegetation and crops through the supply of mineral nutrients. Indeed, the perception of soil as the ultimate control on the development of plant communities has been a central paradigm of plant ecology for at least a century.

In a parallel development, the role of plants in shaping soils was recognized with the beginnings of soil science (Dokuchaev, 1879; cited in van Breeman, 1995). Hans Jenny, in his classic work *“Factors of Soil Formation”* in 1941,

identified plants and animals as one of the primary forces in the genesis of soil from bedrock, and acknowledged that soil scientists extending back to the nineteenth century had perceived plants and soils to be a *“coupled system.”* Conversely, the critically important role of plants in causing soils to form from weathered and unweathered rock was elaborated in detailed studies of primary succession on newly exposed substrate by Crocker and Major in 1955. In the past several decades, the multiple forms of interaction between plants and soil have become a major focus for research.

Plant–soil interactions play a critical part in human interactions with the biosphere. Humans create plant communities ranging in complexity from single species of crop plants in agriculture to attempts at the restoration of complex communities; the choice of plants is conditioned by soil qualities and alters those qualities. Human-caused changes in atmospheric chemistry – the addition of nutrients such as nitrogen and sulfur as pollutants, the increase in CO₂ concentration – directly and indirectly affect plants, soils, and the interplay between them. Changes in climate, driven by these atmospheric changes, have similar effects. Human-caused extinction of species, the introduction of species into novel habitats, and the spread of weedy species change plant community composition, thus driving changes in soil. Conversely, the widespread degradation of soils from erosion and overgrazing constrains the kinds of plant communities that can develop, often to the detriment of human society. These are but a few examples of the profound importance of plant–soil interactions in the management, exploitation, and conservation of biodiversity.

Small-Scale Processes: Micron to Millimeter Scales

The Rhizosphere: Structure of the Root/Soil Interface

Plants contact soil most intimately along the surfaces of their roots. The soil in direct contact with the surface of nonwoody roots, the *“rhizoplane,”* differs in biological, chemical, and physical characteristics from the *“bulk soil”* (Figure 3(a)). The chemical and physical influence of the root surface on the soils decreases rapidly with distance from the root surface; thus, there is a cylinder of *“rhizosphere”* soil that is influenced by the root but not directly in contact with it. Its width varies with the texture and mineralogy of the soil and the diameter and physiological activity of the roots, being from <1 to several millimeters. The rhizosphere changes longitudinally along the root with distance from the root tip, root age, physiological stress to the plant, and degree and type of mycorrhizal infection (Figure 3(a)).

The rhizosphere is most strongly affected by rhizodeposition, the transfer of organic substances from the root into the rhizosphere. This material includes whole cells sloughed from the root cap and the epidermis, secretions of mucilage from these cells, and soluble materials leaked from intact cells and cracks caused by emerging new lateral roots (*“exudate”*). These materials mix with polysaccharide secretions of the adhering bacteria. The mucilage, or *“mucigel,”* lubricates the root surface as it pushes past soil particles and helps to maintain the physical continuity between the root and the bulk soil.

Figure 2 Feedback processes in plant–soil interactions. Changes in plant growth, physiology, and so forth, and changes in plant community composition can alter soil properties, which in turn will drive further changes to the plants. Conversely, soil properties that constrain the patterns of plant growth, physiology, and community composition will be affected by the plants that grow under those conditions. Positive feedbacks will cause the soil–plant system to evolve in a particular direction, unless deflected by a disturbance external to the system. Conversely, negative feedbacks will maintain the system in a constant state.

Figure 3 (a) A schematic diagram of the rhizosphere, illustrating different zones of the root tip (root cap, zones of cell elongation, and epidermal cell lysis), different types of mycorrhizal fungal growth (endomycorrhizal and ectomycorrhizal), and rhizosphere soil. The diagram also illustrates the zone of decreasing root influence with distance from the soil. (b) Distribution of microorganisms with distance from the roots, reproduced from Bazin *et al.* (1990) in Lynch JM (ed.) *The Rhizosphere*. New York: John Wiley and Sons; different species of microorganisms utilize substrates directly derived from roots or secondary materials produced by other microbes in adjacent zones.

In addition, the mucigel may adsorb nutrient ions, especially cations, and prevent their removal from the root surface by leaching. **Table 1** illustrates the diversity of compounds released from various species. The relative proportions of each class of compound may vary with position along the root; for example, amino acids are released in higher amounts near the root tips than farther back.

Studies in a variety of plants have shown that approximately 10–20% of the carbon fixed during photosynthesis is released to the soil through these mechanisms. This rhizodeposition accounts for 40–90% of the total amount of carbon transferred to the roots from the shoots; the remainder is respired by the root tissues or is used to construct new root biomass. Commonly cited values of 10–100 mg g⁻¹ root dry weight for soluble substances and 100–250 mg g⁻¹ root for insoluble materials give some indication of the amounts released. The amounts of carbon transferred from the shoot to the root system and the fraction of that carbon that is released to the soil vary greatly with plant species and soil conditions (**Table 2**), mycorrhizal infection, soil microbial abundance, and soil physical conditions. The total amounts of carbon involved in the transfer can be quite large (an estimation is 1.2 t C ha⁻¹ year⁻¹ to 7.5 t C ha⁻¹ year⁻¹).

The effects of this input of carbon and nitrogen to the rhizosphere is a large increase in the density, diversity, and biomass of the microbiota in the rhizosphere, compared to the bulk soil. Cell counts of microbes in the rhizosphere are usually in the range of 10¹⁰–10¹² cells cm⁻³, compared to 10⁹ cells cm⁻³ in bulk soil. **Figure 3(b)** illustrates a typical distribution of microbes with respect to the root surface. Rhizosphere microbial cell densities: bulk soil cell densities range from <1 for microalgae to >24 for many bacteria; for most microbial groups, ratios are >5. Successions of different microbial species occur (a) over time, as newly produced root tips extend into the soil and are colonized, (b) over the length of the root (from root cap to zones of suberization and secondary thickening), and (c) with distance out from the root surface. Not only is the population of microbes in the rhizosphere larger than in the bulk soil, but it differs in composition. Bacteria are more abundant than fungi, whereas the reverse is often true in the bulk soil, and more species of bacteria may be found in the rhizosphere. Several genera of bacteria capable of fixing atmospheric N₂, including *Enterobacter*, *Klebsiella*, *Azotobacter*, *Azospirillum*, *Bacillus*, *Pseudomonas*, and *Clostridium*, are only found in the rhizosphere; these nonsymbiotic bacteria may (but not always) contribute to

Table 1 Compounds identified in root exudates, classified by general type^a

Type	Compounds
Simple sugars	Hexoses (glucose, fructose, galactose), pentoses (arabinose, xylose, rhamnose), di- and oligosaccharides (wide variety), uronic acids, amino sugars
Amino acids	α -Alanine, aspartic acid, phenylalanine, glutamic acid, leucine, serine, threonine α - and γ -Aminobutyric acids, α -aminoadipic acid, many others
Aliphatic acids	Formic, acetic, oxalic, citric, malonic, tartaric, malic, succinic, lactic, palmitic, stearic, oleic, linoleic, linolenic, others
Aromatic acids	p-Hydroxybenzoic, ferulic, o-cumaric, gallic, vanillic, sinapic, shikimic, trans-cinnamic
Complex carbohydrates	Polygalacturonic acid, other hydroxy-, keto-, di- and tri-carboxylic acids
Enzymes	Several phosphatases, peroxidase, invertase, urease, β -glucosidase
Vitamins	B group, biotin, pantothenic, nicotinic acids, thiamin, pyridoxine, riboflavin
Proteins and peptides	Unspecified
Plant hormones	Auxins, gibberellins, kinetins, ethylene
Other	Isoflavonoids, thiophenes, benzofurans, terpenes, lectins, phytoalexins, alcohols

^aCommonly occurring and representative specific compounds are listed; in all cases, a very large number of specific compounds have been identified in each chemical class. greater plant growth. Species of *Pseudomonas* are particularly important, as many have been found to benefit plant growth. The composition of the rhizosphere biota changes rapidly (within months) in response to changes in the species composition of the plant community, demonstrating the close coupling of the rhizosphere community to the species-specific morphology and physiology of root systems. Variation in the

abundance and diversity of plant pathogens also reflects the differences in rhizodeposition among plant species.

Structural complexity in the zone of root/soil contact is provided by extensions of the root surface into the soil matrix. Most plants produce extensive root hairs from cells just distal to the root cap and zone of elongating cells. The zone of root hair development extends only a short distance along the root (1–4 cm), as the epidermal cells producing the hairs are sloughed off in more basal areas (**Figure 3(a)**). Production of root hairs is itself affected by soil chemical conditions (e.g., pH, ion concentrations), texture, and water content. This zone provides increased structural complexity (e.g., a greatly expanded root surface area that is in direct contact with soil particles). Structural complexity also results from mycorrhizal infection, particularly by ectomycorrhizae, as fungal hyphae spread out from the root surface into the soil (**Figure 3(a)**). Ectomycorrhizal fungi, in particular, produce large quantities of extraradical mycelium; hyphae may extend for several meters from the host plant. These hyphae greatly expand the contact zone between the root and the soil.

Nutrient and Water Uptake: The Function of the Root/Soil Interface

Nutrient supply to plants, at the scale of the root surface and the immediately adjacent soil, is a complex function of the chemistry of individual nutrient ions. The availability of nutrients other than nitrogen is ultimately determined by the chemistry of the soil minerals present, which in turn reflects the geology of the parent material. Weathering releases these nutrients from the crystalline lattice of the minerals into solution, making them available for uptake; however, both physical and chemical weathering rates are themselves strongly affected by vegetation. Roots penetrate cracks and fractures in bedrock, widening them, allowing water to penetrate, and promoting chemical weathering. Chemical weathering depends on the supply of protons for the dissolution and transformation of soil minerals. Plant-derived sources supply most of the acidity involved in weathering; these include CO₂ from root and microbial respiration, which forms H₂CO₃ in the soil solution, organic acids in root exudates and the products of microbial decomposition of plant tissues, and hydrogen ions released from roots in exchange for nutrient cations. Soil genesis also results from the chelation and mobilization of iron and aluminum by the organic acids. As different species of plant generate different types and amounts of organic acid formation, the composition of the plant community strongly affects the nature of the weathering and pedogenic processes that take place. Thus, processes at the scale of the root surface result in broad-scale patterns of correlated vegetation and soil development.

Plant-mediated weathering and pedogenic reactions generate a supply of nutrient cations; their availability for uptake depends on a different set of intersecting plant–soil processes. This includes the diffusion rates, exchange, adsorption, and precipitation chemistry of each element, patterns of water movement through the soil, the morphology of the root system, the amount and diversity of mycorrhizal fungi, and the physiology of uptake by the roots. Nutrients are brought to the

Figure 4 The relative importance of different aspects of root activity in the uptake of several nutrients. Reproduced from Jungk in Waisel Y, Eshel A, and Kafkafi U (1991) *Plant Roots – The Hidden Half*. New York: Marcel Dekker Inc., with permission from Marcel Dekker Inc.

root surface in the mass flow of water and through diffusion; roots encounter nutrients as they grow through the soil. The relative importance of each pathway varies with the different elements (Figure 4). The availability of sparingly soluble elements, such as iron and manganese, may be enhanced by siderophores in the exudate. These are nonprotein-forming amino acids, which complex with these metals, facilitating their mobility and uptake. Organic acids help to mobilize metal nutrients by lowering pH, and help to solubilize P by preferentially binding to the metals. For diffusion-limited nutrients such as P, zones of depletion develop within the rhizosphere (Figure 5(a)); this does not occur with highly mobile ions such as NO_3^- (Figure 5(b)). The size of the depletion zone reflects the balance of supply (diffusion and mass flow) and demand (uptake rate).

Unlike the nutrient cations derived from soil minerals, the availability of nitrogen depends on the microbially mediated decomposition of plant-derived organic matter. It is often assumed that the supply of readily metabolizable carbon from root exudate will promote increased nitrogen mineralization because it relieves carbon limitation, this is not always the case. Theoretical studies have suggested that the net effect of exudates on nitrogen dynamics will depend on the C:N ratio of the exudates relative to that of the indigenous organic matter of the soil, so that balance between the release of N through mineralization versus immobilization in new microbial biomass will vary with the quality of the exudates. Several studies with herbaceous plants have found that the presence of rhizosphere microbes can increase availability of N to the plants, but the effect varies with the availability of N from the soil and the kind of plant grown. Alternatively, N

(a)

(b)

Figure 5 (a) Observed patterns of P depletion with distance from the surface of roots of maize and rape; the zone of low P concentrations adjacent to the root is an indicator of the distance that root hairs grow outward from the root surface. (b) Calculated depletion curves (as percent of bulk soil concentration) of three nutrients; the depletion rate out from the root surface depends strongly on the chemical mobility (combination of diffusivity and likelihood of adsorption, precipitation, or other immobilizing chemical processes). may be immobilized within the microbial communities in response to root exudation. Thus, the effects of root exudation on the supply of mineral N to plants is a complex function of the kind of plant, the nature of the organic matter in the soil, and the amounts and composition of the exudate. Root exudate may decrease or increase N availability, even in different horizons of the same soil.

Not least among the effects of roots on the rhizosphere soil is the alteration of soil pH. In addition to the excretion of organic acids and CO₂, roots exchange protons and hydroxyl ions for nutrient ions, particularly ammonium (NH₄⁺) and nitrate (NO₃[−]). Because nitrate is rapidly taken up when it is present, a net imbalance of anion and cation uptake occurs. Maintenance of electroneutrality during this requires that an anion be extruded in exchange for the nitrate ion; this anion is usually hydroxyl (OH[−]). Conversely, hydrogen ions (H⁺) are excreted during uptake of ammonium. Soil pH can rise as much as two units within the rhizosphere when nitrate uptake is rapid, whereas it may decrease by up to two units when all uptake is in the form of ammonium.

Physical Structure of Soil

Plants modify the physical arrangement of soil particles in a variety of ways. In most soils, the grains of mineral material and the soil organic matter are bound together in aggregates. In the rhizosphere, the mucigel produced jointly by the plant and the resident microbes bind clay minerals together into microparticles of about 50 µm diameter. Fungal hyphae can bind together these microparticles into larger aggregates of 1–2 mm diameter. The products of root growth (and root-supported mycorrhizal fungal growth) are especially important in stabilizing the aggregates over time. Moreover, different plant communities create different quantities and sizes of soil aggregates, depending in part on the morphology of the root system and the extension and mass of mycorrhizal hyphae.

Pore size distributions are also affected by roots through several other mechanisms. Alternate wetting and drying of the

soil induced by transpiration can affect cracking patterns, especially in clay-rich soils. Roots also preferentially grow into larger pores, or zones of lower penetration resistance, and may thereby enlarge them. The death and decay of roots also creates macropores or channels of highly porous organic matter; these large voids provide preferential pathways for the flow of water. Finally, the degree of contact between the root surface and the soil varies with root age, amount of exudation, and root physiological status (e.g., hydration).

Roots also lose molecular oxygen to the soil, as air diffuses from leaves and stems through lacunae in the cortex tissues and through cracks in the surface of the root epidermis. This “radial oxygen loss” is particularly large in wetland plants, in which the root cortex develops extensive air spaces (“aerenchyma”) through the degradation of cell walls. Root oxygen loss can be sufficiently high to alter the reduction–oxidation potential of the surrounding bulk soil (Table 3). As a result, a zone of 2–3 mm of oxidized soil (often apparent as a coating of orange–red iron oxide grains) may develop around the root surface under anoxic, waterlogged conditions. This zone of oxidized iron minerals acts as a trap for other metal ions in the soil, such as cadmium, copper, lead, and zinc, which become enriched in the surface concretions as much as 10-fold greater than the bulk soil concentrations. Moreover, by maintaining a higher redox potential in the soil, denitrification and methanogenesis may be inhibited; this both decreases the presence of toxins (methane) adjacent to the root surface and also alters the net carbon and nitrogen balance of the soil.

Several species of wetland plants, including the yellow water lily (*Nuphar lutea*) and common reed (*Phragmites australis*) take advantage of a thermal diffusion mechanism to develop positive air pressures in young leaves and drive a mass flow of air into the roots. This air can effectively oxygenate long rhizomes (> 2 m long in *Phragmites*) plus the surrounding soil. Only a few wetland plants employ mass flow to move air through the roots and back to the leaves; the rest rely on diffusion of oxygen through the aerenchyma. In most plants, however, the aerenchyma also provides a pathway for

Table 3 Effects of roots on reduction–oxidation potential (Eh, mv) of wetland soils, mediated by root oxygen loss

venting methane produced in anoxic soil to the surface; plant stems account for >90% of the methane release to the atmosphere from waterlogged soils.

Soil physical properties, including texture, bulk density, temperature, and moisture-holding ability, affect the number, size, diameter, and branching patterns of roots in a great diversity of ways. In many plants, clayey soils inhibit root growth compared to sandy soils. This reflects the ability of the roots to grow into pores between soil particles and to penetrate aggregates of particles. Mechanical impedance, reflected in the soil's bulk density, affects all aspects of root growth, root system morphology, and uptake functions. Temperature is another factor affecting root growth; optimal temperatures vary among species and are usually lower than the optimal temperatures for shoot growth. Aeration and moisture status, which are inversely related to each other, are jointly controlled by climate and by the transpiration rate of the plant community. Temperature, aeration, and moisture content also affects the morphology of the root system (root diameters, density of root hairs, and frequency of branching). Not surprisingly, texture, mechanical impedance, temperature, moisture, and aeration are interrelated (as they all are affected by particle size distribution), and their effects on root growth are interactive.

Mesoscale Processes: Centimeters to Meters

The microscale interactions between root surfaces and the adjacent soil are part of a larger set of interactions that occur over scales of centimeters to meters. Strategies of resource allocation by whole plants, including changes in growth rate, differential growth of above-ground and below-ground tissues, changes in root longevity and turnover, and physiology (i.e., in changing metabolic capacity for nutrient uptake) affect the vertical and horizontal extent of root penetration through the soil, thereby affecting the spatial extent over which microscale plant-soil interactions occur. At this larger scale, the deposition of litter from the above-ground tissues becomes as important as the patterns of root growth within the soil; indeed, litter input may dominate the biological processes within the soil. However, spatial variation in soil properties, driven by topography, bedrock geology, and other exogenous factors, also affects root system morphology and growth, and condition the fate of the litter.

Nutrient Acquisition and Root Growth: Individual Plants

The acquisition of nutrients and water is strongly affected by the architecture and size of the root system, a function of the allocation of photosynthate below ground. Conversely, the availability of nutrients and water molds the growth of the root system, thus setting up a feedback interaction. The metabolic capacity to absorb nutrients not only varies among plant species, but also varies within an individual as the availability of nutrient elements changes. Nutrient uptake capacity is often inversely related to availability, because transport systems in the root cell membranes increase in activity as nutrients become more limited in supply. For

example, barley plants growing in nitrogen-limited cultures have uptake rates of both ammonium and nitrate more than 200% greater than plants growing with excess N; similarly, phosphate uptake rates increase by 400% in phosphorus-limited cultures, and sulfate uptake rates increase by almost 900% in sulfur-limited culture. Similar inverse relationships between availability, as measured in soil solutions or extracts, and short-term uptake rates have been found for a wide range of wild plants, including both herbs and trees. However, while relative uptake capacity varies within a species inversely with the availability of nutrient elements, absolute rates of uptake of plant species from low-nutrient environments may be less than, equal to, or greater than plant species found in high-nutrient environments. Thus, the effects of nutrient availability on root physiology depend on both the species of plant and the variation present in the soil.

Nutrient acquisition is also affected by the abundance and distribution of the roots. Different kinds of plants are characterized by differences in the relative allocation of biomass to roots and shoots (**Figure 6**). In general, grasses tend to have higher relative allocation to roots than do woody plants, although trees and shrubs in highly nutrient-limited environments, such as alpine tundra or bogs, have higher root:shoot ratios than do woody plants from more nutrient-rich environments such as tropical or temperate deciduous forests.

Root systems also adjust to varying nutrient availability by changes in morphology (length, diameter, branch density, etc.). Root length density (the length of roots per unit volume of soil) commonly increases in zones within the soil that have higher concentrations of limiting nutrients, as has been frequently demonstrated in experiments (**Figure 7**). However, such responses are not seen in all species, and the response to variations in nutrient availability depends on a plant's tendency to produce thick versus thin and fast-growing versus slow-growing roots. Increases in root length in one area, in response to a patch of high nutrient availability, are often compensated for by decreases in other parts of the root system. Furthermore, nutrient concentrations in plant tissues do not necessarily increase, and plant growth also often does not show an overall increase, suggesting that plants compensate for increased growth in one part of the root system in response to increased nutrient availability by decreasing growth elsewhere.

The response also depends on the plant's tendency to produce herringbone versus dichotomous patterns (**Figure 8**). The optimal response depends in part on the plant's ability to allocate carbon to the root system (versus shoots, leaves, or reproductive structures), the size of an area of increased nutrients, and the chemistry (i.e., the diffusivity) of the nutrient at stake. Research by A. Fitter has shown that herringbone patterns are most efficient for mobile nutrient ions, but herringbone and dichotomous patterns are equivalent for immobile ions. Others have shown that herringbone patterns are more common in roots growing in infertile soils; the lower amount of branching allows the root system to explore a larger volume of soil. In fertile soils and in nutrient-rich microsites, branching patterns become more dichotomous; this pattern presumably permits more intensive and complete exploitation of the soil resource.

Figure 6 The relative allocation of biomass to roots, as (a) the percentage of total plant biomass and (b) with respect to shoot biomass, for plants from various habitats. Reproduced from Klepper in Waisel Y, Eshel A, and Kafkafi U (1991) *Plant Roots – The Hidden Half*. New York: Marcel Dekker Inc.

The heterogeneity of root systems in response to soil conditions reflects the high degree of heterogeneity in soil conditions at scales of centimeters to tens of meters. In agricultural fields, for example, chemical and physical soil properties vary significantly between points that are only tens of centimeters apart, despite the apparent uniformity that might be expected from the nearly flat topography, homogenization of the soil from plowing, and planting of a single species of crop plant (Figure 9). Extreme patchiness in one soil resource may not be paralleled by similar patchiness in other resources in the same site; the distribution of mobile, limiting elements like nitrate can vary greatly among points only 3 cm apart whereas immobile, nonlimiting elements (P, K) do not vary, even over large distances.

In natural communities, significant variation in nutrient concentrations and nutrient supply rates (e.g., nitrogen mineralization rates) have been documented in soils beneath different co-occurring species of grasses and trees. Spatial variation in soil properties is also generated by topographic variation. Even small changes in elevation or geomorphic position (e.g., hill crest, upper and lower slope positions, valley bottoms) are associated with differences in soil profile development, accumulation of organic matter, soil texture, the mineralization rates of nutrient elements, and gaseous losses through microbial processes such as denitrification. At scales of tens to hundreds of meters, differences in plant community composition are clearly correlated with differences in soil properties related to topography.

Spatial heterogeneity of soils is particularly strongly developed in plant communities in which either plants are patchily distributed over otherwise barren ground (typical in many arid ecosystems) or in which differing life-forms (e.g., trees and grasses) are interspersed (e.g., savanna ecosystems). In deserts, the scattered plants form “islands of fertility” because of their ability to trap both plant litter and wind-blown fine soil particles. The soils within and beneath the scattered shrubs or tussock grasses in these systems have higher amounts of nitrogen, phosphorus, organic matter, silt or clay-sized particles, and moisture than the intervening bare areas. Similarly, patches of woody vegetation within grasslands accumulate higher amounts of nutrients and organic matter, again leading to patches of higher fertility within the grassland landscape. Plasticity of root system morphology and physiological capacity allows plants and communities to respond to this spatial variation in soil properties.

Nutrient Acquisition and Root Growth: Stand Scale

The response of individual plants to variation in soil properties manifests itself at the level of the community as changes in root biomass and the production and mortality rates of the roots. Many studies have shown that root biomass tends to be lower in more nutrient-rich sites, and experimental studies in which nutrients (particularly nitrogen) are added often confirm these observations. Similarly, it has been noted that

Figure 7 The results of a classic experiment by Drew in which the roots of barley plants grew through zones of nutrient-enriched soil. Control plants received all nutrients throughout the root system; the other plants received high concentrations of the target nutrient only in the middle of the root system. Reproduced from Drew MC (1975) Comparison of the effects of a localized supply of phosphate, nitrate, ammonium and potassium on the growth of the seminal root system, and the shoot, in barley. *New Phytologist* 75: 479–490.

plants typical of infertile sites have a higher ratio of root biomass to above-ground biomass than do plants from fertile sites. In a comprehensive review of available literature on nutrient cycling and root production, *Vogt et al. (1986)* found that the mass of fine roots in forest ecosystems is higher in forests with larger amounts of nitrogen in the forest floor, implying that the biomass of roots increases when nitrogen is sequestered in compounds that decompose slowly and accumulate in thick forest floors. This supports the idea that root biomass is greater in infertile than in fertile soils.

Rates of production and mortality of fine roots also respond to nutrient status, although experimental studies have documented both increases and decreases in response to nutrient additions. For example, *Vogt et al. (1986)* suggested that the rate of root turnover (input of new roots per year) is higher

in forests with smaller amounts of nitrogen input in litterfall (an index of nitrogen limitation), but experimental addition to N to northern hardwood forests caused a decrease in mortality rates of fine roots. The contradictory data may reflect differences between the “normal” growth patterns of roots relative to the inherent fertility of the soil and the response of existing root systems to large, sudden changes in fertility induced by experimental nutrient additions.

Competitive Interactions between Plants and Microbes

As the plant community and the soil microbiota require the same resources (nutrients and water), there may be competition between the microbiota and plants. Microbial

demand for nitrogen is closely tied to the availability of degradable carbon, as carbon is often considered to be their most limiting resource. In this context, the likelihood of competitive interactions with plants depends on the C:N ratio of the available carbon resources; root exudates tend to have low C:N ratios (about 15:1), litter normally has high C:N ratios ($>30:1$, and $>100:1$ for woody plant tissues), and soil organic matter ratios are in the range of 10–20. Theoretical analyses have suggested that the relative mineralization versus immobilization of N derived from root exudates varies in

Figure 8 Alternative patterns of root growth. Dichotomous branching systems have more internal segments of the root system, compared to herringbone branching systems. The internal segments, or links, tend to be larger in diameter and therefore are more “expensive” to construct and maintain (in units of carbon fixed during photosynthesis). Plastic responses of roots to heterogeneous soil conditions involve changes in branching pattern, branch number, and length, branching angle, root diameter and tissue density (observed as changes in specific root length and area, or length and area per unit root mass), and density of root hairs. Reproduced from Fitter A in Waisel Y, Eshel A, and Kafkafi U (1991) *Plant Roots – The Hidden Half*. New York: Marcel Dekker Inc. and other papers.

relation to the relative availability and quality of the soil organic matter, where “quality” refers to the metabolic capacity of the microflora to degrade the components of the organic matter. When N is limiting (i.e., when C:N ratios are high), microbes may take up mineral N from the same sources (soil solution, exchange surfaces) that plants use, resulting in competition.

Experimental additions of mineral N (NH_4^+ , NO_3^-), to forest soils have shown that the microbiota captures a substantial proportion, often a majority, of the added N, but that nitrification rates are decreased when plants are present. These results suggest that while the microbiota compete successfully for mineral N in solution, plants can limit the availability of NH_4^+ to the ammonia oxidizers (nitrifiers). However, long-term studies suggest that although microbes may outcompete plants for mineral N in the short term, the long-term activity of root systems, compared to the shorter, more localized bursts of activity of the microbes in response to changing temperature and moisture regimes, may allow plants to compete successfully. In this regard, the influence of plants on the soil moisture regime, through uptake of water and loss in transpiration, may indirectly affect competitive interactions for N by causing limitation of microbial activity due to soil drying. Furthermore, competition for N may be modified by differential use of the inorganic and organic forms of N in the soil.

Litter Inputs to the Soil: Effects of Plant Tissue Chemistry

Perhaps the most widely studied and best-known interaction of plants and soil is the supply of organic matter to the soil through the deposition of litter. Litter deposition includes “fine litter,” the leaves, herbaceous stems, and smallest woody twigs, “coarse woody debris,” the large twigs, branches, and boles of shrubs and trees, “greenfall,” of leaves and leafy twigs clipped by herbivores such as squirrels, and root litter, the

Figure 9 Spatial patterning of physical and biological soil properties in a soybean field in Michigan (US). Units: (a) net N mineralization, $\text{mg N g}^{-1} \text{ d}^{-1}$; (b) microbial biomass, $\text{mg C g}^{-1} \text{ soil}$; (c) peak plant biomass, g m^{-2} (d) nitrate, $\text{mg N g}^{-1} \text{ soil}$, (e) elevation, m. Reproduced from Robertson GP, Klingensmith KM, Klug MJ, Paul EA, Crum JC, and Ellis BG (1997) Soil resources, microbial activity, and primary production across an agricultural ecosystem. *Ecological Applications* 7: 158–171, with permission from ESA.

dead roots of all size classes. However, most measurements of "litter" refer only to fine litter, as this is most easily measured. Litter is the largest source of organic matter supplied to the microbiota of the soil, and thus it fuels all of the microbial processes responsible for decomposition, nutrient cycling, and reduction-oxidation reactions of soil minerals and also is the ultimate source of the soil organic matter.

Litter inputs vary widely in quantity and timing. Tropical rain forests may have $>2000 \text{ g m}^{-2} \text{ year}^{-1}$ litterfall, whereas tundra ecosystems may have $<200 \text{ g m}^{-2} \text{ year}^{-1}$. Deposition of fine litter is seasonal in temperate zones and continuous in the tropics, but the formation of coarse woody debris may be sporadic (i.e., large inputs following major storms, or infrequent inputs at any time of year). Amounts of coarse woody debris are comparable (approximately $120\text{--}3000 \text{ Mg m}^{-2} \text{ year}^{-1}$) but much more patchily distributed. Greenfall production is also sporadic, as it reflects the population dynamics of the herbivorous insects or mammals that cause it. The timing of root death is quite variable among ecosystems; in some forests, root growth and death are pulsed, but in other sites, production and mortality may occur simultaneously and not in synchrony with seasons. Assuming that root populations are at steady state, so that root production rates can be used as an estimate of root litter deposition rates, the amounts of root litter production similarly range from roughly $100 \text{ g m}^{-2} \text{ year}^{-1}$ to $1,700 \text{ g m}^{-2} \text{ year}^{-1}$.

The ratio of above-ground to below-ground litter inputs is also quite variable among ecosystems (Table 4). Root litter inputs can be very high in grassland ecosystems as well, with ratios of below-ground:above-ground litter mass much greater than 1. The variability of the relationship between above-ground and below-ground litter production was clearly demonstrated by Raich and Nadelhoffer (1992), who found no statistically significant relationships between the amount of fine root production and the amount of above-ground litter production over a wide geographic range of locations and forest types.

As important as the quantity and timing of input of litter is, the chemical composition of the plant tissues is perhaps more important as the ultimate control on the activity of the soil microbiota. The ability of microbes to decompose the litter material depends on (a) the ratio of carbon to nitrogen and (b) the chemical forms in which the carbon occurs. Carbon occurs in plant tissues in several forms, including "non-structural carbohydrates," which include soluble and membrane-bound contents of the cytoplasm and vacuoles. Cell walls contain cellulose (an unbranched chain of glucose

residues), hemicelluloses (branched chains of glucose residues), and pectins; these materials are variably bound to lignin, a complex phenolic material that provides strength to the tissues. Because of its molecular structure, lignin is extremely resistant to decomposition; relatively few soil microorganisms have the requisite enzymes to degrade it. Other important carbon-containing compounds include polyphenols and tannins; these compounds act both as deterrents to herbivores and as inhibitors of decomposition. The nitrogen in plant tissues is largely found in protein; approximately 50% of the total leaf nitrogen may be in enzymes and structures associated with photosynthesis.

A large number of studies over many years have shown that the ability of the soil microbiota to decompose plant material depends on both the C:N ratio and the lignin:N ratio. The C:N ratio describes the quality of the substrate (e.g., litter material) relative to the demand by the microbiota for both energy and nitrogen. As the C:N ratio of the microbiota is lower (approximately 3–5 for bacteria and 10–12 for fungi) than any plant material (range from about 12 for leguminous herbs such as vetch and alfalfa to 400–600 for hardwood and coniferous sawdust, respectively), decomposition will be slowed in proportion to the energy/nutrient imbalance between the decomposers in a given soil and the particular substrate available. However, decomposition rates are also affected by both the absolute amount of lignin in the plant tissues and by the lignin:N ratio. Table 5 illustrates typical results of a

Table 5 An example of the role of plant tissue chemistry in regulating decomposition rates

Plant	%N	%Lignin	%C	C:N	k
White spruce	0.52	13.1	47.0	89.4	–0.757
Douglas fir	0.61	20.5	46.7	76.6	–0.850
Balsam poplar	0.58	13.6	44.6	76.9	–0.907
Aspen	0.64	14.1	45.5	71.1	–1.351
Grass	0.81	15.2	45.8	56.5	–1.391
Dogwood	0.78	7.5	41.5	53.2	–1.706
Rose	1.15	3.4	44.5	38.7	–1.841
Cow-parsnip	1.31	7.0	39.6	30.3	–2.550

Tissues were allowed to decompose in laboratory microcosms for 4 months. Regression analyses of the data showed that the best predictors of mass loss were the C:N ratio, %N and lignin:N, in that order. Nitrogen content was more important early in decomposition; lignin became more important as decomposition proceeded.

comparative study of decomposition rates (k) of different plant materials, showing the close relationship between tissue chemistry and decomposition. Although studies differ in identifying C:N, lignin:N, nitrogen concentration or lignin concentration as the primary factor regulating decomposition rates, and in describing the relationship between decay rate and lignin:N as linear or nonlinear, almost all identify some subset of these characteristics as critical.

Decomposition not only produces CO₂, but also results in (a) the production of microbial metabolic products that are stable in the soil, and form the passive or long-term component of soil organic matter, and (b) the mineralization of nutrients such as nitrogen, sulfur, and phosphorus, which are bonded to carbon. Release of these nutrients into the soil solution is, again, a function of the availability of the nutrients in the plant litter substrate relative to the demand by the microbiota, as modified by the efficiency of assimilation of the microbes. Thus, the chemical composition of the plants that compose a community will affect the rates of accumulation of organic matter in the soil, as well as the rates of mineralization of limiting nutrients for plant growth. Alterations of plant community structure, through disturbance, succession, or management, can precipitate changes in nutrient cycling rates and carbon sequestration rates that create feedbacks to the plant community. For example, extensive browsing by moose on birch trees in boreal forests allows white spruce to grow up in their place; the switch from readily decomposable birch leaves to recalcitrant spruce needles causes decreases in the availability of nitrogen, which in turn favors the slow-growing spruce more than nitrogen-demanding birch. This positive feedback maintains spruce-dominated forests until stand-destroying fires permit birch to become re-established.

Interactions with the Soil Biota

Plant interactions with the soil biota are a crucial component of the processes that control litter decomposition, nutrient cycling, and plant community composition. Over the past decade, the understanding of plant–soil biota interactions has increased dramatically. The soil food web involves a large number of organisms, ranging from bacteria and fungi, to consumers over a wide range of sizes (nematodes at the microscale of microns to insect larvae at the macro scale of millimeters to centimetres.) The soil fauna includes organisms that not only are feeding on each other, but also herbivores and pathogens that are directly affecting plants. Plant inputs to the soil food web – root and shoot litter inputs – are often categorized by their chemical characteristics (*see* Litter Inputs to the Soil: Effects of Plant Tissue Chemistry), with more readily decomposed materials providing the base for a bacterially mediated food web, whereas more recalcitrant materials provide the base for a fungal-based food web. Each food web involves numerous kinds of organisms, and the food webs tend to be longer (more steps) than above-ground food webs, and highly multitrophic. Direct and indirect interactions between plants and the soil fauna characterize the wealth of interactions. Direct interactions involve the herbivores, pathogens, parasites that directly consume plant tissue, infect the roots, and thereby affect plant survival and growth. These

organisms include pathogenic nematodes and fungi and insect larval root feeders as the two most prominent groups.

Plant pathogens exert important effects on the plant community through differential survival and growth of infected and uninfected plants. Numerous experiments, and agricultural practice, have shown that multiple generations of the same plant species in a given soil allows pathogen populations to build up, exerting a negative feedback on the plant community (or significant loss of plants in an agricultural planting of a single crop species). The pathogen load induced by training a soil with a given plant species has been widely explored as the mechanistic basis for many plant community changes. For example, nonnative plant species often become established in a region without their associated community of soil pathogens. Several studies of invasive herbs and forbs in grasslands, and one study of a woody plant invader, show that the reduction in negative plant–soil feedback resulting from the lack of pathogens and other soil faunal enemies can contribute to invasive success of the nonnative species. For example, the dune grass *Ammophila arenaria* supports generalist pathogens in its invaded ranges, but not the species-specific pathogens found in its native range and responsible for its decrease in abundance during normal dune succession. Similarly, as species from southern Europe invade communities in northwestern Europe, they experience less negative soil feedback (negative effects on growth after a first generation of plants has “trained” the soil by promoting associated plant pathogens) than do species native to northern Europe. Black cherry (*Prunus serotina*), an invasive species in Europe that is native to the US, also experiences greater effects of soil pathogens in its native soil than it does in soils in the invaded range, suggesting that the lack of negative feedback from the soil pathogen population facilitates the invasion.

Plant interactions with mutualists in the soil biota are as important in altering plant communities and providing plant–soil feedbacks as interactions with pathogens and parasites. Nitrogen-fixing bacteria are well-known symbionts, and nonsymbiotic nitrogen-fixing bacteria that are associated with plant roots can also be important. Both symbionts and associative bacteria increase the amount of available nitrogen both to the specific plants with which they are associated, and overall in the community, over time. The classic example of a dramatic change in plant communities due to nitrogen fixation is the invasion of *Morella faya*, a leguminous tree, which supports nitrogen fixation, unlike the native vegetation. The presence of the invasive tree and its symbiont results in an increase in N inputs from fixation from 0.2 kg ha⁻¹ year⁻¹ to 18 kg ha⁻¹ year⁻¹.

Mycorrhizal fungal symbionts also have complex interactions with plant communities. More than 80% of plant species have associated mycorrhizal fungi, which may be symbionts, nonobligate mutualists, or even function as parasites. Although most mycorrhizal fungi are thought to be nonspecific in their associations with particular plant species, the identity of particular fungal species can affect both plant performance, and the effects of the mycorrhizal infection on community dynamics. A number of studies have shown that the identity and diversity of arbuscular–vesicular mycorrhizae affects the composition and diversity of the plant community, with increases in plant diversity being associated with the

presence and diversity of mycorrhizal fungi. However, not all studies find such results; the effects of mycorrhizal fungi on plant community structure can vary with soil conditions and fertility, and the identity of both plant species and fungal species.

Plants also interact indirectly with soil organisms that are not parasites, pathogens, or mutualists. These organisms include the vast bulk of bacteria, fungi, nematodes, protozoa, mites, collembolan, enchytraids, earthworms, and other organisms that make up the soil biota. The primary pathway of interaction is the supply of decomposable substrate to this biota, both through dead root inputs and above-ground litter inputs. Both the quantity and the chemical quality of this organic input have a profound influence on the function, biomass, and composition of this fauna, as has been shown in numerous studies. Conversely, the mineralization of nutrients by this biota provides the major feedback to the plant community. The supply of mineral nutrients, and the form in which they are supplied, determine plant community composition, plant productivity, and interspecific interactions among the plant species. Plants that produce recalcitrant litters (high C:N ratios, high lignin content, high lignin:N ratios, high polyphenol content) tend to promote fungal-dominated soil microbial communities, with fungal:bacterial ratios approaching 1.0, slow rates of mineralization, organic forms of nutrients (e.g., amino acids for nitrogen, organophosphorus compounds for phosphorus) present, and a soil fauna that is dominated by fungal-feeding organisms. These food webs are associated with slow plant growth, low net primary production, and species that are poor competitors. In contrast, plants producing labile litter (low C:N, low lignin, low polyphenols) stimulate a bacterial-based food web, with species that are primarily bacterivores as the primary consumers. The macrofauna also tends to differ, with earthworms less common in acidic, fungal-dominated humus materials of slowly-decomposing litters and more common in the less acidic,

bacterial-dominated richer soils of rapidly decomposing species. Indeed, the chemical and physical characteristics of plant litter has proven to be more important than climate or any other source of influence on the activity of the soil biota that carry out decomposition and nutrient cycling. The differential in nutrient availability in turn drives differences in plant species composition, as described above in the discussion of litter inputs. In brief, plants and the soil biota are tightly linked through the reciprocal influences on litter qualities and quantities: as these ecosystem properties change, nutrient supply changes, with differential effects on plant species and therefore on the composition of the plant community. Changes to the plant community in turn affect the quantity and quality of litter returned to the soil biota.

In sum, plants and the soil biota interact through both direct and indirect pathways (Figure 10). Although there are numerous variants on the specific mechanisms and pathways, they all involve a process by which the soil biota can influence competitive interactions among plant species, and therefore plant community composition. This may be through direct subsidies from mutualists, or indirect supply of nutrients from the saprotroph web. Because plant traits, especially the chemistry and physical structure of litter, have such a dominating effect on the activity and composition of the soil biota, any change in the species composition, or relative abundance of plant species in a community can result in a cascade of effects on the soil biota. These effects in turn affect the cycling and accumulation of carbon, nitrogen, phosphorus, and other nutrients within the soil, thus affecting ecosystem cycles. Recent work has shown, for example, that above-ground food webs and trophic cascades result in such changes, mediated by changes in plant composition and the ensuing litter inputs to the soil. Herbivores alone affect the soil biota through their differential effects on plant success, as well as the physical effects of trampling and the chemical inputs from their waste. But predators can affect the soil biota also: predation-driven

Figure 10 Pathways of interactions between the plant community and the soil biota. Both direct (symbiont, predators and parasites) and indirect (nutrient availability mediated by the saprotrophic soil biota) pathways are shown. Reproduced from Bardgett RD and Wardle DA (2010) *Aboveground-Belowground Linkages*. Oxford: Oxford University Press.

changes in the herbivore community can bring about change in plant community, and the resulting changes in plant inputs to the soil drive changes in decomposition and nutrient cycling resulting from changes to the soil biota.

Large-Scale Interactions: Stands and Biomes

The small- and medium-scale interactions described earlier contribute to larger-scale patterns that reflect, on one hand, the structure and composition of the whole plant community and, on the other hand, geographical effects on soil structure. These patterns may change over time, in response to successional changes in the plant community and in response to the geomorphological evolution of the landscape.

Geographic Patterns of Soils in Relation to Vegetation

In the classic formulation of Hans Jenny, the formation of soils reflects not only climate, bedrock geology, time, and local topography, but also vegetation. Over the broad geographic scale of biomes, regular patterns of soil characteristics are associated with patterns of plant community composition (Table 6). In polar regions, extreme climatic conditions constrain the development of vegetation; without organic matter inputs, microbial activity is low, weathering processes are extremely slow, and soils are barely more than bedrock material. In boreal and temperate forests, differences in the kinds of plant species result in differences in the rates of decomposition and accumulation of soil organic matter and the production of organic acids; these processes in turn affect the kinds of chemical weathering and pedogenic processes that occur. In grasslands, the high production rate of fine,

nonwoody roots introduces both organic matter and the root-associated processes described earlier to depths of several meters; rapid decomposition and incorporation of surface litter combined with the pattern of root production create soils with very different properties than those of forest soils. Indeed, many studies have examined soils beneath forests that developed following long-term management of an area as grassland or cropland; rapid changes in the amounts, spatial distribution, and chemical quality of the soil organic matter cause changes in cation and metal chemistry associated with the changed chemistry of organic acid production and correlated changes in nitrogen availability and microbial activity.

Variations in Soils within Biomes: Effects of Species Composition

Within biomes, soil properties vary geographically with the species composition of the vegetation. The differential effects of particular tree species on soil properties result in parallel differences among stands when different species are dominant. These effects are clearly shown when single-species plantations are compared (Figure 11). The effects of different plant species on soil acidity is particularly important, as changes in pH and acidity affect the mobility of cationic nutrients and can result in large losses through leaching. The differences are due to both differences in the amount of cations stored in the vegetation and also to differences in the loss of cations in water leaching through the profile. Cations lost through leaching may cause a permanent change in the quality of the soil, unless weathering rates are equal to loss rates.

Successional changes in plant communities may in part be driven by plant-caused changes in soil structure and chemistry. In many communities, high rates of nitrogen cycling

Table 6 Regional characteristics of soils and vegetation

<i>Vegetation</i>	<i>Climate</i>	<i>Soil order</i>	<i>Speed of pedogenesis</i>	<i>Weathering processes</i>	<i>Horizons present</i>
Cold desert	Extremely dry, cold	Entisols	Extremely slow	Precipitation of carbonates	Only C
Tundra	Dry, cold	Inceptisols	Slow	Organic acid formation clay weathering Fe-hydroxides	Thin O, A, B
Boreal forest	Very moist, cold	Spodosols	Slow to moderate	Organic acid leaching Fe-hydroxides clay weathering	Thick O, A, leached E differentiated B
Temperate forest	Moist, mesic	Inceptisols alfisols	Moderate	Organic acid formation clay weathering Fe-hydroxides	Thin O, A, variable E, deep, differentiated B
Grassland	Moist to dry mesic	Mollisols	Moderate	Nonmobile organic acids; CaCO ₃ precipitation, Fe-hydroxides	O absent, deep A, thin B, little differentiation
Savanna	Moist to dry warm	Vertisols, Udisols	Fast	Nonmobile organic acids, clay weathering, variable CaCO ₃ and Fe–OH formation	No O, deep A, differentiated, very deep B
Desert	Dry warm	Aridisols	Slow	CaCO ₃ precipitation Fe–OH formation	No O, A, shallow B
Tropical rainforest	Wet, very warm	Oxisols	Very fast	Mobile organic acids Fe, Al–OH formation strong clay weathering	Thin O, A thin E, very deep, differentiated B

Figure 11 Variations in soil properties among different tree plantations. Data from Binkley D and Valentine D (1991) Fifty-year biogeochemical effects of green ash, white pine, and Norway spruce in a replicated experiment. *Forest Ecology and Management* 40: 13–25, with permission from Elsevier.

(mineralization and nitrification) are observed early in succession, in association with herb- or shrub-dominated communities, but these rates decrease markedly as trees come to dominate the community. These decreases in nitrogen cycling rates are associated with changes in litter chemistry (more recalcitrant material, lower nutrient concentrations) and in root quantities and distributions. A good example of this process is demonstrated by boreal ecosystems. Early in succession, N-fixing alders (*Alnus* spp.) in shrubby communities support high rates of nitrogen mineralization and nitrification; these rates decline rapidly when the alders are replaced by poplars (*Populus balsamifera*) and white spruce (*Picea glauca*). The decline in nitrogen cycling rates that accompanies the successional shift from alders to poplars is driven not only by differences in the N content of the litter, but also by the presence of high concentrations of tannins and phenolics in the spruce needles. The tannins inhibit microbial activity, whereas the phenolic compounds are used as a carbon source by the microbiota; however, both compounds result in N immobilization.

Invasions of trees into grasslands are associated with a wide range of changes in soil properties. For example, water content of the soils changes due to (a) differences in inputs (stem flow and drip from canopy leaves accentuate inputs, thick litter layers promote infiltration, but high rates of interception by the canopy can reduce total precipitation reaching the surface, and interception within the litter layer can prevent moisture from reaching mineral soil), (b) differences in soil porosity (large pores and channels associated with the growth of woody roots, and the growth of such roots to greater depths than the grasses), and (c) differences in loss (higher transpiration rates by trees, but shading decreases soil temperature and therefore evaporation rates, as does the accumulation of thick litter layers). Large withdrawals of cationic nutrients occur, which are sequestered in the larger amounts of perennial biomass of woody plants. Nitrogen becomes increasingly unavailable, as recalcitrant, lignin-rich litter accumulates. Finally, greater acidity of leaf litter tissue, greater production of organic acids from litter, and protons released through cation and ammonium uptake all drive acidification of the soil profile, with concomitant changes in both leaching loss of cations and weathering rates.

Just as changes in species composition may drive changes in soil properties, soil properties can affect successional patterns. Fertile soils are thought to support faster rates of succession (i.e., rates of species replacement), but with lower plant diversity than infertile soils. However, a wide variety of patterns have been observed, and many of the studies involve applications of nutrient fertilizer to experimental plots. Additions of nutrients have promoted the growth of early successional annual species, or the persistence of perennial herbs at the expense of woody pioneers, but opposite results have also been observed.

Successional processes have also been related to the mechanism of competition among plant species for soil resources. Tilman (1988) has shown that competitive ability is related to the capacity of a plant to obtain nutrients from the soil solution and thereby reduce concentrations below the minimum needed for competitors; this ability is balanced by the need to compete for light, so that the outcome of competition (and thereby the composition of a community) reflects the tradeoffs in competing for different resources. Plant growing on infertile soils tend to have lower nutrient requirements (low uptake rates but compensating low growth rates) and higher rates of nutrient conservation (higher efficiency of nutrient use) compared to plants typically found in fertile soils. The tradeoffs among characteristics promoting competitive success in infertile soils (strong competition for nutrients) versus success in fertile soils (competition for light being more important) ultimately determine the successional process in a given site.

Successional change can also be driven by negative plant–soil feedback resulting from the promotion of parasites and pathogens. In grasslands, for example, it has been shown that early successional species can create dense populations of their soil-based enemies, resulting in a competitive advantage for later-successional species that are not affected by these populations of parasites and pathogens. Changes in vegetation towards mid-successional stages of herbaceous plants result from this feedback. However, it is not well known whether similar negative feedback processes operate with the woody species that make up later-successional stages.

Clearly, as soil properties themselves are dynamic, and change with changes in species composition, interplant

interactions such as competition will change over successional time as the soil–plant system itself evolves. Such a situation has been observed in the Netherlands, where high rates of atmospheric nitrogen deposition have driven a successional change from heath-dominated (*Erica tetralix*) communities to grass-dominated communities (*Molinia caerulea*). *E. tetralix* is characterized by low growth rates, low rates of biomass loss to shed tissues, herbivory, and so on, and poorly decomposable litter, which supports low rates of mineralization but high rates of sequestration in thick organic horizons. In contrast, *Molinia* is characterized by high growth rates, high rates of tissue loss to shedding and herbivory, and rapidly decomposable litter. As expected, in experiments specifically testing competitive ability, *Erica* is a superior competitor when nutrient supplies are low, whereas *Molinia* is the superior competitor when nutrient supplies are high. Thus, the feedback relationships between plants and soils can drive successional changes in community composition.

Implications for the Management and Conservation of Ecosystems

Clearly, the complex, multiscale interactions of plants and soil affect all aspects of both the biology of plants and the properties of soils. This implies that both purposeful and inadvertent human effects on plant–soil systems will have diverse, perhaps unexpected ramifications, as changes in soils affect plants and *vice versa*. Following are brief discussions of four major areas of current concern, in which plant–soil interactions are likely to play a major role.

Forestry, Agriculture, and Ecosystem Restoration: Human Creation of Ecosystems

Humans create plant communities for a wide variety of purposes, from the production of food, fiber, and fuels to the restoration of “natural” ecosystems and the creation of beauty for its own sake (in gardens and parks). The choice of plant species is often conditioned by soil properties; certain crops cannot be grown in certain soils, or conversely particular soils may be ideally suited to particular crops. Conversely, the choice of crop plant or tree can alter soil properties, in some cases perhaps irreversibly. As described earlier, the substitution of coniferous trees for deciduous trees, a widespread practice because of the rapid growth and high economic value of many conifers, results in acidification, the loss of nutrient cations through leaching, and the creation of thick litter and humus layers. In some cases, foresters use mixtures of tree species that are specifically designed to take advantage of differences in plant–soil interactions among the species. For example, larch (*Larix* spp.) and lodgepole pine (*Pinus contorta*) are often interplanted with Sitka spruce (*Picea sitchensis*) in plantations in the British Isles, because larch and pine promote higher rates of nitrogen cycling and therefore faster growth of the spruce. The increased nitrogen availability results, in part, from more widespread roots of the interplanted pines or larches, which reduce waterlogging in the organic horizon and thereby stimulate mineralization. Nitrogen-fixing

plants are often introduced into both agricultural and forest plantations in order to alter the cycling of N through the soil.

Ecosystem restoration similarly involves the deliberate establishment of particular plant species and species mixtures. The choice of species is most commonly made on the basis of replicating the “natural” community, rather than explicitly with respect to soil properties. However, plant communities are sometimes specifically designed to alter soil properties: the introduction of fast-growing grasses to introduce organic matter in barren soils, and the parallel introduction of N-fixing species into such soils, the use of nutrient-demanding, fast-growing species to remove nutrients (through repeated harvest) from overfertilized fields being restored to native grasslands, or from wetlands being used for waste-water treatment are examples. Conversely, soil properties may unexpectedly affect the course and success of restorations. The potential for such effects is clearly illustrated in efforts to restore coastal wetlands in San Diego, California. Coarse-textured sediments were used to construct the wetland, which were unlike the fine-textured sediments found in naturally occurring marshes. Although the introduced salt marsh plants survived and spread, they only attained about half the height of plants in undisturbed marshes; the cause of the problem was the low storage rate of organic matter in the coarse sediments and the concomitant low intrinsic supply rate of nitrogen from the sediments.

Exotic Species Invasions – Inadvertent Human-Caused Changes in Species Composition

The spread of exotic plant species around the world is recognized as one of the major threats to biodiversity. Plant communities are being altered through invasions of species that in some cases become part of the community, but in other cases exclude and eliminate the native species. These invasions often cause economic problems, as well as challenges for conservation of native communities, as the invading species degrade grazing lands, choke stream channels, or promote wildfires.

These changes in plant community composition are likely to alter soil properties, especially when the exotic species is of a different growth form than the natives or when its litter chemistry is different. Recent studies have shown that, for example, invasions of cheat grass (*Bromus tectorum*) into desert grasslands alters the abundance and species composition of fungi, protozoa, nematodes, and soil invertebrate communities, decreases the abundance of N-fixing lichens, and thereby decreases the amount of nitrogen in the soil. Invasions of exotic shrubs (*Berberis thunbergii*) and grasses (*Microstegium vimineum*) into deciduous forests stimulates increases in nitrification and soil pH. Invasions of the hawkweeds (*Hieracium* spp.) into pastures in New Zealand causes the accumulation of nitrogen, but decreases soil pH. Invasions of grasses (*Melinis minutiflora*) into Hawaiian shrub lands stimulates increases in net nitrogen mineralization rates. It is likely that such changes are widespread and may affect the ability of resource managers to remove the exotics and restore the native plant communities.

Nutrient Pollution – Inadvertent Human-Caused Changes in Soil Properties

The profound and far-reaching changes in atmospheric chemistry that are accompanying the spread of industrial society around the world include greatly increased inputs of several nutrients to soil–plant systems, through the deposition of particles and the dissolution of soluble ions in precipitation. The most important changes include greatly elevated deposition of nitrogen and sulfur. As these are both important plant nutrients and as their chemistry is intimately linked with other chemical and biological processes within the soil, a cascade of interactive changes to the soil–plant system are taking place in many places around the world.

Deposition of sulfates at rates below the level that directly injures plants still causes problems through soil acidification. Leaching of sulfate in soil water carries with it nutrient cations, and in soils with low base saturation and a parent material that supplies few cations through weathering, cations can become seriously depleted. Calcium, an essential element for the integrity of root function, is particularly strongly affected. Hardwood forests in New Hampshire (US) that have received large inputs of sulfate for several decades have prematurely stopped growing, and their tissues show abnormally low concentrations of calcium. Depletion of nutrient cations is accompanied by increases in the concentration of aluminum ions in the soil solution and on exchange sites, and the aluminum can be directly toxic to plants. Depletion of calcium also leads to increased sensitivity to frost damage of needles, due to change in the structure of cell membranes, as has been demonstrated for declining red spruce in the eastern US.

Nitrogen deposition to ecosystems is now occurring at double the estimated rates prior to the industrial revolution. Nitrogen originates from agriculture (applications of fertilizers and manures, and the planting of N-fixing crops), combustion (automobiles, power plants, and also forest burning), and waste disposal (e.g., sewage). Although nitrogen is considered as the most important limiting resource in most terrestrial ecosystems, an excess does not simply alleviate stress on plants. As was discussed earlier, plants growing in nutrient-poor soils have a variety of characteristics, including patterns of both root and above-ground morphology and physiology, characteristics of life history, and intrinsic growth rates, which adapt them to such habitats and, which contrast strongly with the characteristics of plants found in nutrient-rich soils. Added nutrients often cannot be absorbed or assimilated by such plants, nor can they respond with increased growth. Rather, species adapted to nutrient-rich soils become capable of competitively displacing these species. Thus, many ecosystems that had been subjected to limiting supplies of nitrogen have undergone profound changes in species composition. The substitution of grass for heather in European heathlands, as discussed earlier, is a case in point. Similar changes in native plant communities are occurring elsewhere in the industrialized world. And because communities found in infertile soils tend to have high diversity of plants, including many rare species, the increasing dominance of nitrophilous species may threaten many of them.

Nitrogen additions to soil not only affect the plant community through competitive displacements and substitutions, but also affect the internal nitrogen dynamics of the soil.

Evidence from a variety of ecosystems has shown that N additions stimulate intrinsic mineralization processes, thus accentuating the effects of added N. Moreover, changes in the microbiota under conditions of high N inputs can result in the development of acid-tolerant nitrifiers; the increased levels of NO_3^- not only cause changes in plant community composition, but cause leaching of cations and thus changes in soil chemistry. As plant community composition changes, the chemistry, amount, and timing of litter inputs will change, as will all other components of the plant–soil system. The long-term effects of this chain of linked changes can only be guessed.

Changing CO_2 in the Atmosphere – Inadvertent Human-Caused Changes to the Soil–Plant System

The rising concentration of CO_2 in the atmosphere is expected to affect virtually all aspects of the plant–soil system. The topic can be touched on only briefly here, simply to note the major processes and interactions that are anticipated. Plants are expected to respond to increasing CO_2 by increasing their overall rate of production (particularly C_3 plants), increasing the allocation of carbon to below ground (including root growth, root turnover rates, root respiration rates, and rhizodeposition rates). Water use efficiency and nutrient uptake rates also often increase in experimentally enriched plants. Changes in litter chemistry (increased C:N ratios, increases in lignin, phenolics, or tannins) are anticipated but have yet to be clearly demonstrated. However, individual species responses have proven to be highly variable; studies of the growth response of a wide range of species has shown that changes in growth rate can range from a 25% decrease to a 200% increase. However, it is clear that virtually all aspects of plant morphology and chemistry that have been shown to affect soil properties are likely to change, precipitating changes in the soil in accordance with the processes discussed in this chapter. **Figure 12** illustrates the complexity of the possible responses. The research done over the past decade has demonstrated that climate change and the linked changes in atmospheric chemistry have both direct effects, through changes in temperature and precipitation, and indirect effects, through changes to plant growth from both these climatic changes and the increase in CO_2 concentrations in the atmosphere on plant–soil interactions. Moreover, changes in the distribution of both above-ground and below-ground herbivores and predators in response to changing climate will have ramifying effects on soil food webs and nutrient cycles, largely mediated by changes in the plant community. These types of interactions have now been demonstrated in many studies, but there is much still to be learned about how climate change and CO_2 changes affect plant–soil interactions.

Although a large amount of research is currently being conducted on these linkages, the complexity of the problem and the variability in response among different plants and in different soils make the discovery of general patterns and predictability difficult and yet to be achieved.

Biodiversity and Ecosystem Function

The effects of changing plant community diversity on the structure and function of soil is among the most important

Figure 12 A schematic outline of the potential changes in the soil–plant system that may be induced by changes in atmospheric CO₂ concentrations.

current topics of research. Several studies utilizing experimental grasslands have shown that such ecosystem processes as nitrogen mineralization, carbon accumulation and mineralization, nitrogen concentrations, soil respiration, and litter decomposition rates are altered (often decreased) by decreases in plant diversity, but other studies, including studies in forested ecosystems, have presented contradictory results. In many cases, particular species or particular classes of species (e.g., nitrogen-fixers) have large effects. In addition, responses of soil processes to changes in plant diversity often are largest in comparing small numbers of species; once the plant community reaches a moderate number of species (three or four), there is no further change as plant species diversity increases. Reciprocal effects of diversity within the soil microbiota and soil fauna on the plant community are largely unknown.

The effects of changes in diversity within the plant community to the biology, chemistry and physics of soils, and *vice versa*, will be among the most important questions to be addressed in the future.

Pollinators, Role of

David W Inouye, University of Maryland, MA, USA

Glossary

Phenology The timing of recurring plant and animal life cycle stages, such as flowering or emergence of pollinators.

Poricidal anthers Anthers that function similarly to salt shakers; they must be vibrated at the right frequency (by buzz pollinators) to dispense pollen grains through the pores at the end of the anthers.

What is Pollination?

Pollination is the transfer of a pollen grain (male gametophyte) to a flower's stigma (receptive surface of the female reproductive organ), where it may germinate, grow through the style, and fertilize an ovule to produce a seed. This transfer can be accomplished by abiotic agents such as wind and water, but the majority of pollination is effected by animal pollinators seeking nutritional rewards such as pollen and nectar, or sometimes other resources such as warmth, floral perfumes, oils, or resins, or even reproductive opportunities through mimicry of potential mates by ornate flowers. The relationship between the plants and pollinators is commonly assumed to be mutualistic, with the plants benefiting from the transfer of pollen and the pollinators receiving a nutritional or other reward, but there are also instances in which the plants appear to provide no reward and cases in which pollinators may also be seed predators. This rich diversity of relationships has been fertile ground for investigation by pollination biologists for hundreds of years. The importance of pollination in agriculture has also been a powerful stimulus for the study of plants and pollinators.

There is an important distinction to be made between "flower visitor" and "pollinator." Visitors to flowers (anthophilous animals) cannot be assumed to be pollinators, as in reality they may be nectar or pollen thieves which, owing to a mismatch in morphology or an unusual behavior, do not pollinate while removing floral resources. For example, "base workers," or insects that remove nectar from between the petals of a flower with an unfused corolla, or insects too small to contact the reproductive parts of a flower, would not be pollinators despite the fact that they may spend a lot of time in harvesting nectar. However, their activities may be detrimental to the flowers' pollination, as pollinators may be deterred by finding no nectar in flowers already visited by nectar thieves. Similarly, a small insect that collects pollen from anthers but never contacts stigmas is an example of a pollen thief that does not pollinate. Simple experiments, such as collecting stigmas of flowers to confirm pollen deposition after a visit, or the observation of transfer of a pollinium (a packet of pollen, characteristic of flowers in the Orchidaceae or Asclepiadaceae), can help to distinguish between visitors and pollinators. Unfortunately, many animals observed on flowers are probably best categorized as flower visitors because this kind of confirmation of pollination has not been conducted. It is surprising that much remains to be learned about the pollinators

of many important agricultural species, in addition to other plants.

Although the origins of much of what we know about pollination biology lie in the realm of natural history, pollinators are now studied from many scientific perspectives, including foraging behavior, physiological ecology, coevolutionary interactions, and the perspective of trophic network theory. The significance of native pollinators in agriculture and the conservation biology of endangered pollinator species are now also commonly studied. Techniques such as telemetry, harmonic radar, and even GPS tags are now providing insights into pollinators that were not previously possible. For all these reasons pollinators are appreciated for the economic value of their ecosystem service of pollination, their esthetic value, and tractability for experimental studies.

The Diversity of Pollinators

The list of species of animals that serve as pollinators is long and diverse. The largest group of pollinators is insects, but both flying and nonflying mammals, birds, and at least one reptile have been recorded as pollinators. **Table 1** shows a list of pollinator classes for the world's wild flowering plants (the angiosperms; ~240,000 species), and estimates of the number of species in each. Much work remains to be done to confirm the activities of these taxa as pollinators, but these numbers are the first estimates available.

Invertebrate Pollinators

Although flower visitation has been observed by species from at least 16 orders of insects, only four of them include many species that regularly pollinate flowers and that seem to have been involved in coevolutionary interactions with plants. These are the beetles (Coleoptera), flies (Diptera), butterflies and moths (Lepidoptera), and ants, bees, and wasps (Hymenoptera). In addition, the thrips (Thysanoptera) include some pollen-eating species that may be pollinators, some stoneflies (Plecoptera) and true bugs (Hemiptera) will visit flowers and eat pollen and nectar, and some lacewing (Neuroptera), scorpionfly (Mecoptera), and caddisfly (Trichoptera) species eat nectar. Additional work is needed to confirm whether most of these lesser-known flower visitors are indeed pollinators.

Table 1 Pollinator classes for the world's wild flowering plants (~240,000 angiosperm species)

Pollination categories	Estimated pollinator taxa
Wind (abiotic)	20,000
Water	150
All insects	289,166
Bees	40,000
Hymenoptera (bees and wasps)	43,295
Lepidoptera (butterflies and moths)	19,310
Diptera (flies)	14,126
Coleoptera (beetles)	211,935
Thrips	500
All vertebrates	1221
Birds	923
Bats	165
Mammals other than bats	133

The numbers are "the number of species comprising the invertebrate and vertebrate genera, families, and orders in which there are more known effective pollinators than there are pollen or nectar cheaters, robbers, or avoiders".

Beetles

Beetles have been abundant since at least the Mesozoic, and it is likely that some of them have been flower visitors since the origin of the earliest angiosperms. For example, the current association of beetle pollination (cantharophily) with primitive woody angiosperms (*Magnolia* is an example) probably dates back to the evolutionary origins of both groups. Beetle pollination is considered to be the most primitive type of pollination by animals, and is not very important in cool temperate regions. It is most common in the moist tropics, and to a lesser degree in arid areas. Beetles constitute the largest order of insects, and some of this diversity is thought to have arisen through the same evolutionary radiation of flowers and insects during the Tertiary that led to the origin of the other major orders of flower-visiting insects.

Flies

Flies are probably the second most common order of flower visitors (after Hymenoptera). Fly visitors from at least 71 families of Diptera to flowers in 137 plant families have been recorded in the literature (compilation by Inouye). The families Syrphidae (hoverflies), Bombyliidae (bee flies), and the Muscidae are especially common as flower visitors. In tropical areas, the diversity of flower-visiting Diptera can rival or exceed that of the Hymenoptera. For example, 4856 species of Diptera are recorded from Australasia from flower-visiting families, compared with ~2570 bees (superfamily Apoidea), whereas for the Neotropics the estimates are >2940 species for Diptera and 5630 species for bees (Roubik, 1995). In some parts of the world, including the Faroe Islands, New Zealand, and Australia, where bees are nonexistent or relatively rare, flies have filled that ecological niche of pollinators.

Pollination by flies (myophily) is economically important; in tropical areas flies are the primary pollinators of cacao and also pollinate mango, cashew, and tea. Roubik (1995) lists pollinators of 785 species of cultivated plants in the tropics,

and 26–31 of these plants are apparently pollinated only by flies, 32–33 by flies as the primary pollinators, and 87–101 more by flies as secondary pollinators. In Europe, flies are used commercially to pollinate protected crops of onion, chive, carrot, strawberry, and blackberry. In both tropical and temperate areas, flies appear to be more important as pollinators than has been generally recognized, and there is a need for additional research on them.

In addition to the more specialized flower-visiting flies, carrion, and dung flies are pollinators of some plants, in a category of pollination called sapromyophily. The basis for attraction of the flies is floral fragrances that mimic rotting flesh or dung, and typically the flies do not receive any nutritional reward for their visits. Some of the most spectacular flowers in the world are fly pollinated, such as the inflorescence of the titan lily (*Amorphophallus*, not really a lily), which can reach 10 ft tall and is called the corpse lily for its fearsome odor; it attracts and is pollinated by flies. Another example is the largest flower in the world, *Rafflesia*, found in Borneo, which can reach a meter in diameter and smells like rotting meat. Blood-feeding Diptera such as mosquitoes and biting flies (Tabanidae; horseflies, deerflies) are also sometimes pollinators, attracted to flowers by the nectar they offer.

Some flies have remarkably long tongues that permit them to collect nectar from correspondingly long corolla tubes. A tabanid fly in South Africa that visits flowers with long corolla tubes has a proboscis length of up to 35 mm, whereas another species in the Nemestrinidae has a proboscis up to 57 mm (and flies with the proboscis folded under its body and sticking out behind). Some bee flies (Bombyliidae) also have relatively long tongues.

Flies provide one of the few examples of a system in which a flower species (globeflower, *Trollius*) has an obligatory pollinator species (several species of *Chiastocheta* flies) whose larvae are also seed predators, consuming a proportion of the seeds. There are some interesting evolutionary dynamics that lead to a stable mutualism between globeflowers and the globeflower flies.

Butterflies and Moths

The Lepidoptera (butterflies and moths), as a consequence of their two distinct lifestyles as primarily herbivorous larvae and commonly flower-visiting adults, have dichotomous relationships with plants. In at least one case, the pollination of yucca, the act of pollination by yucca moths is accompanied by oviposition and the larval moths are seed predators. Although not all Lepidoptera feed as adults, most, if not all, do depend on nectar as a source of both sugars and amino acids. Some of the longest lived of all butterflies, the neotropical *Heliconius* species, also feed regularly on pollen by collecting it on their proboscis and regurgitating nectar on the pollen mass to leach out amino acids. Female butterflies of some species are dependent on the amino acids and sugars they collect in nectar to provide nutrients needed for making eggs, so the more nectar they can collect the more eggs they can lay. The floral rewards sought by Lepidoptera are not always nutritional; some species are attracted to flowers by the pyrrolizidine alkaloids that they produce, which the male butterflies require for the production of pheromones, for mating success, and for the establishment of multispecies leks. Lepidoptera, as

agents of natural selection, may be responsible for much of the diversity of defensive chemicals in plants (to deter herbivorous caterpillars) as well as diversity in flowers and the rewards they offer.

Two families of moths stand out as pollinators. One is the hawk moths (Sphingidae; also called sphinx moths), and the other is the noctuid moths (Noctuidae; the largest family in the order Lepidoptera). The hawk moths are strong and agile fliers that maintain very high body temperatures (e.g., as high as 46 °C) while in flight. Some diurnal species are easily mistaken for hummingbirds (e.g., the European hummingbird hawk moth, *Macroglossum stellatarum*). Some hawk moths are migratory, and (in successive generations) may move hundreds of kilometers during a summer in North America. Hawk moths include the pollinators with the longest known tongues; most of these extraordinary species are found in Madagascar. Darwin measured nectar spurs in some orchids from Madagascar that were 29 cm long, and concluded that there must be moths there that have proboscis lengths of the same length. Forty years after his prediction, a hawk moth with a proboscis that reaches greater than 24 cm in some individuals was found and given the name *Xanthopan morgani praedicta*. There is actually a large guild of long-tongued hawk moths and flowers with matching corolla lengths in Madagascar.

Some noctuid moths are long-distance migrants, flying distances as far as 1600 km. One species is reported to travel as much as 1000 km in a day when migrating from the Baltic States to Britain. This presents the opportunity for some very long-distance gene flow on the part of their food plants! Some species migrate vertically, moving up in altitude some time during the year to avoid unfavorable seasonal weather. Before these migrations, the moths may store substantial quantities of fat, and at least one such species was an important part of human diets; the bogong moth (*Agrostis infusa*) was collected while estivating in the Snowy Mountains by aboriginal Australians.

Ants, Sawflies, Wasps, and Bees

The Hymenoptera (ants, sawflies, wasps, and bees) are the largest and most diverse group of pollinators. Ants are only rarely recorded as pollinators, although they are not uncommon as flower visitors collecting nectar. One suggestion for why there are not more species of plants adapted for pollination by ants is that the antibiotic and other secretions that ants have on their exoskeletons are detrimental to pollen survivorship and growth. Sawflies are more common as pollinators. They have herbivorous larvae, and in some cases the adults restrict their flower visits to the larval host plant. The adults may also eat flower parts in addition to nectar and pollen. Flower visitation by wasps has been studied in part because of interest in attracting and sustaining populations of parasitoid wasps (which prey on pest insects) in agricultural situations. But predatory and social wasps have also been recorded as flower visitors and a few species of plants are specialized for pollination by pseudocopulation by male wasps (see Pollination by Deception). Some of the most specialized relationships between plants and pollinators are those between species of figs and the wasps that pollinate them; many of those relationships are reported to involve single

species of wasps pollinating each fig species. The wasp larvae develop in some of the seeds produced by the pollinating activity of their mothers.

There are fewer species of bees than beetles, but a much higher proportion of bees are pollinators than are beetles. Almost all species of bees, both adults and larvae, are dependent on flowers for pollen and nectar as nutritional resources, and of all the insects bees are the most highly adapted for flower visitation and pollination. Their behavior, morphology, and senses of vision and smell all appear to be adapted for finding and collecting floral resources. For example, the trichromatic color vision of bumble bees and honey bees includes ultraviolet, which allows them to see the ultraviolet reflectance patterns that many flowers use as nectar guides or a petal color. Humans cannot see these patterns without the help of cameras.

Although pollen (primarily for feeding larval bees) and nectar (both a larval and adult resource) are the most common resources collected by bees, some flowers offer oil as a reward. The oil is collected by bees in the family Anthophoridae; females of these species have absorbent brushes for holding the oil and sharp edges on their legs that are used to squeeze the oil out so that it can be mixed with pollen as food for larvae. Some bees collect resin as a floral reward, which they then use in nest construction.

Pollination by bees (melittophily) is very important for agriculture (see Pollinators in Agriculture and their Economic Value). The social bees are the best-known crop pollinators, and are the species most commonly managed for pollination or honey production. These include honey bees (*Apis*), bumble bees (*Bombus*), and stingless bees (*Trigona*). The presence of large quantities of honey (concentrated nectar), pollen, and larvae makes social bee nests an attractive target for insects and vertebrates that prey on nests and adult bees. Bee-eaters and honey guides are two examples of Old World birds that specialize on such resources, and honey and wax are also attractive resources collected from wild colonies by humans in some parts of the world.

Vertebrate Pollinators

Mammals

Although invertebrates are the most common pollinators, mammals, birds, and lizards have also been documented as pollinators. Mammalian pollinators include both bats, some of which primarily eat nectar and pollen, and nonflying species such as some Australian marsupials. Most bat pollination occurs in the tropics, but some migratory bats are important pollinators in temperate North America to about 30° N. In the Old World species of the family Pteropidae, fruit bats, are important pollinators, whereas in the New World flower-visiting bats are confined to the family Phyllostomidae. Although pollination by bats (chiropterophily) is geographically widespread, the other mammalian pollinators are more restricted and less common as pollinators, including lemurs in Madagascar and several species of Australian marsupials such as sugar gliders, honey possums, and some marsupial mice. There are scattered reports of other mammals, including mice and giraffes, which may serve as pollinators in unusual cases.

Vertebrate taxa other than mammals or birds are only rarely reported as pollinators; there are a few reports of lizard pollinators on islands.

Birds

Bird pollination (ornithophily) is common in many parts of the world. Several families of birds are primarily nectarivorous and undoubtedly include important pollinators. These include the hummingbirds (Trochilidae; New World), honeyeaters (Meliphagidae; Australia, New Zealand, and parts of Asia), sunbirds (Nectariniidae; Africa and Southwest Asia to the Philippines), sugarbirds (Promeropidae; South Africa), flowerpeckers (Dicaeidae; Asia and Australasia), and Hawaiian honeycreepers (Drepanididae; Hawaii). Other families that include some nectarivores or scattered records of flower visitation include the Thraupidae (honeycreepers and some tanagers; New World), Icteridae (orioles; New World), Zosteropidae (white-eyes; Africa, Asia, and Australia), and Psittacidae (lorikeets and hanging parrots; Southeast Asia and Australasia). A number of flower-visiting birds are recently extinct in the South Pacific islands, but in at least one case an introduced species has taken over the role of a pollinator for some of the endemic plants that were pollinated by the extinct birds.

Coevolutionary History of Plants and Pollinators

The “abominable mystery” that Darwin referred to, the origin and relationships among flowering plants, is still being revealed. Beetle pollination is thought to be the primitive condition in flowering plants, but by 100 Ma butterflies and moths had joined beetles as important pollinators. Recently discovered fossil evidence indicates that the origin of the angiosperms (flowering plants) may date back as far as the Late Jurassic, suggesting that the origin of the coevolutionary relationship between flowers and pollinators may also be older than previously thought. Much of the tremendous biodiversity found in the flowering plants is thought to have arisen through evolutionary interactions with pollinators, and certainly much of it is maintained through their flower-visiting activities that result in the production of seeds. The remarkable diversity of flower size, shape, odor, rewards, color, and pollination mechanisms is the result of these coevolutionary relationships.

Pollinators in Natural Systems

Obligate and Facultative Mutualisms

The relationships between plants and pollinators range from obligate to facultative in nature. Although one study in Brazil found that 43% of the plants studied were visited by only a single species of pollinator, other studies have found tens of visitor species to a single plant species. In only a few cases have researchers quantified the relative importance of different species in cases with multiple pollinators of a single plant species. A common finding of multiyear studies is variation, both temporal and spatial, in abundance of these different

groups of pollinators. The visitors to a single plant species can include diverse taxonomic groups, for example, both vertebrate and invertebrate pollinators (e.g., hummingbirds and bumble bees). By having several groups of potential pollinators, it is more likely that these plants will not suffer from pollen limitation, or a shortage of pollination; if one group of pollinators is unusually low in abundance at a particular site or in a particular year, it is likely that another group will not be. Thus it can be important to have a diversity of pollinators available.

The obligate nature of some plant–pollinator relationships extends also to pollinators, as some insects appear to visit flowers of only a single species of plant. In such cases, there must be a good match in the phenology of life cycles of both plant and insect to ensure success for both partners, and one concern about global climate change is the potential for such phenological relationships to become mismatched. There are similar cases of plant species visited by only a single species of pollinator. Although a plant or pollinator may thus have an obligate relationship with a single partner, the partner may be involved in relationships with multiple species.

Although we assume that most plant–pollinator relationships are mutualistic in nature, some examples appear to involve a mixture of positive and negative interactions from at least the plant’s perspective. Several studies have demonstrated seed predation or other forms of herbivory by insects that may also serve as pollinators. These examples include beetles and palms, moths and yuccas, wasps and figs, as well as flies and moths and some flowers that they pollinate. Some of these relationships (e.g., yucca flowers and their moths) can be farther complicated by the presence of closely related species of insects that are herbivores but not pollinators. Much detailed study is needed to dissect the complicated interactions in such relationships.

There is no doubt that long-lived or highly mobile pollinators must interact with a large number of plants, as their life spans or travels extend beyond the temporal or spatial availability of single plant species. Thus a group of plant species, even if they are not sympatric, could be considered mutualists if in concert they sustain and share a particular pollinator. This kind of multispecies relationship has significant conservation implications, as it may be necessary to conserve plant species flowering widely separated in time and space to conserve a (e.g., migratory) pollinator. This idea has led to the concept of a “nectar corridor” to sustain long-distance migratory pollinators. Hummingbirds are an example of a species that requires nectar resources along a long migratory route; many North American species overwinter in Mexico but reproduce during the summer as far north as Alaska. Monarch butterflies are another example, with individual butterflies traveling thousands of miles from summer breeding grounds to wintering areas in Mexico, and then partway back the next spring.

Cheaters in Pollination

Pollen and Nectar Robbers

The nutritional rewards that pollinators find in flowers, pollen, and nectar are sometimes harvested by flower visitors that

may pierce or bite holes in the flowers to obtain the resources “illegitimately.” Some species of birds (*Diglossa*, the flower-piercers) and bees (*Xylocopa*, carpenter bees; some short-tongued *Bombus*, or bumble bees, and some stingless bees) may obtain most of their nectar in this fashion. Once these primary nectar robbers have created holes, other species may learn to use them, as secondary robbers. Typically, these flower species that are robbed have long corollas, and the nectar robbers do not have mouthparts long enough to obtain the nectar without robbing. Although biologists at least as far back as Darwin have assumed that nectar robbing would have a significant negative influence on the robbed plants, more recent evidence suggests that in fact most insect nectar robbers that have been studied have either a beneficial or neutral effect on the plants. In the process of moving around on the flowers, or perhaps while collecting pollen from the same flowers, robbing insects may effect pollination. Even in the absence of such a direct effect, robbers may indirectly increase the fitness of plants they rob by influencing the behavior of legitimate pollinators. The reduced quantity of nectar in a robbed flower may induce a legitimate pollinator to visit more flowers or to fly greater distances between flowers, thereby increasing gene flow.

Pollination by Deception

Cheating in pollination biology is not restricted to the pollinators. Plants also provide fascinating examples of deception, attracting some pollinators by falsely advertising opportunities for feeding or sex. The orchid family is perhaps the best known in this regard, as many species of orchids have flowers with no nectar, and pollen that is not accessible or attractive to pollinators. In such species, it appears that the pollinators gain nothing from visiting (and pollinating), and quickly learn to avoid the flowers. Other orchids have flowers that, in both morphology and odor (production of insect sex pheromones), resemble female insects well enough that males attempt to copulate with them and in the process pollinate (pseudocopulation).

Pollinators in Agriculture and their Economic Value

Our knowledge of the pollination biology of crop species is surprisingly sparse. For example, the pollination requirements of about one-third of the crop species grown in the European Union are still unknown. These plants include at least 264 species that are cultivated as crops, or gathered from the wild, for human or livestock food, or for the essential oils they contain. The best-known pollinators of cultivated food plants are honey bees, which have been widely introduced around the world (see Conservation Biology and Pollination). However, honey bee populations in the US have been decimated in recent years by the introduction of two species of parasitic mites, and are also being threatened by introduction of a hive beetle. Most feral colonies of honey bees in the US have disappeared since the arrival of the *Varroa* and tracheal mites in the 1980s, and the number of managed colonies has declined to less than a half of its peak. This decline has resulted in a growing reliance on and appreciation of the roles of other, native, species in the US and elsewhere as pollinators of crops.

The rapid growth of the almond industry in California around the beginning of the twenty-first century has had a significant impact on commercial beekeeping of honey bees. Almonds require pollination to produce fruit, and the value of the crop is so high that almond growers are willing to pay significant fees (e.g., ~\$140 per colony in 2010) for use of the bees during the few weeks of flowering. Beekeepers from as far away as Florida have moved bees to California to take advantage of these fees, creating shortages for some other parts of the country.

These problems with honey bee availability have also prompted some attempts to quantify the economic value of pollination services provided by both managed and wild pollinators. A recent model estimates that US consumers realize \$1.6–5.7 billion in annual social gains that would be lost if honey bee services for 62 crops were reduced. The potential value of nonhoney bee pollinators in the US agricultural economy can be estimated at \$4.1–6.7 billion yr⁻¹. An estimate of the global value of pollination services has been placed at \$117 billion yr⁻¹.

Introduced Species of Pollinators

Undoubtedly, the largest-scale introduction of pollinators has been the global traffic in the European honey bee (*Apis mellifera*). Such continental-scale introductions have a long history. For example, European colonists in North America imported honey bees as early as 1641. This species went on to establish feral colonies over much of North America and, probably through subsequent introduction, to much of the neotropics. They were also introduced to Australia. Probably, the second largest introduction of pollinators has been the spread of bumble bees (*Bombus*). The first introduction of bees anywhere specifically for pollination was the introduction of European bumble bees to New Zealand in 1885 (to pollinate introduced clover for the introduced cattle), and subsequently they were also introduced to North America. The second successful introduction of a pollinator was a fig-pollinating wasp (*Blastophaga psenes*) into California in 1899.

In these cases, the incentive for introducing bees or wasps was for the pollination of introduced species of plants that were not attractive to or could not be pollinated by native pollinators (e.g., clover in New Zealand and figs in California). More recently, international transport of bumble bees has been the result of their use in pollination of greenhouse crops, especially tomatoes. In the 1980s, techniques were developed for the year-round commercial-scale propagation of bumble bee colonies (which normally have an annual life cycle of a few months). Commercially produced colonies of bumble bees have now largely replaced the tedious hand pollination of tomato flowers with electronic vibrators (tomato flowers produce no nectar, but are visited by bees that “buzz” the flowers to release pollen from poricidal anthers to collect it for feeding to their larvae, and in this process they pollinate the flowers) and the use of chemical sprays to induce fruit set.

In the early 1990s, a European species of bumble bee (*Bombus terrestris*) was introduced to Japan for use in greenhouse pollination; it has subsequently escaped and is now established in the wild. Although an effort is being made to

exterminate the introduced species in the wild (and to develop native species for use in greenhouse pollination), it is likely to be unsuccessful. The phenomenon of “pathogen spillover” has been documented recently for bumble bees, with wild bees found close to greenhouses having a higher incidence of disease than those further away; presumably, this results from contact with infected commercial bees that are foraging outside the greenhouse. There is some suspicion that the loss of a native North American bumble bee species (*Bombus occidentalis*) in much of its former range along the west coast may be a consequence of disease or parasites introduced by the cultivation of colonies in Europe from wild-caught queens that were then reintroduced to the US (having acquired the parasites or diseases during rearing in Europe). Two other species of North American bumble bees may have gone extinct in the past few years, perhaps because of introduced diseases.

Other species of pollinators have also been introduced. The wasp pollinators of figs have been introduced to New Zealand and the US, where they pollinate naturalized figs. The Japanese white-eye, an introduced passerine in Hawaii, has taken over the role of a pollinator of two native plants that lost their original pollinator to extinction. An Asian bee is now the primary pollinator of alfalfa plants grown for seed production in the US and a Japanese bee is used in the US and Canada for pollination of apples. The alfalfa leaf-cutting bee (*Megachile rotundata*) was introduced to North America to pollinate introduced alfalfa, and has also been introduced recently to Australia. Every year, millions of these bees are imported to the US from Canada, where they are raised and then shipped as pupae.

Pollinators as Vectors and Victims of Engineered Genes

As genetic engineering of crop plants has become more common, and as these crops are approved for cultivation in the field, concerns have arisen about the potential for gene flow through pollen transport between the engineered genomes and wild plants. One management tool to prevent, or at least minimize, this potential is to plant a buffer zone of unengineered plants around a field of engineered plants in hopes of intercepting pollinators carrying pollen before they can visit related native plants.

There is also the potential for pollinators to be victims of engineered genes. For example, laboratory studies of monarch butterfly caterpillars showed that if they eat significant quantities of corn pollen from plants engineered to have the *Bacillus thuringiensis* toxin in their leaves, it can kill them. Corn is wind pollinated, and a likely scenario is that large quantities of corn pollen could be distributed onto leaves of milkweed plants at the margins of cornfields. The potential for this to have detrimental effects on the monarch butterfly and other herbivores remains to be studied but may not be as serious as was first feared.

Conservation Biology and Pollination

Threats to Plant–Pollinator Mutualisms

Pollinators now face a large variety of threats of anthropogenic origin (Kearns *et al.*, 1998). These include habitat fragmentation,

a variety of effects of agriculture, pesticides, and herbicides, introduction of parasites and diseases, and the introduction of both pollinators and plants. Fragmentation of habitats is likely to affect nonflying pollinators most strongly, as it may be difficult for them to locate and visit patches of flowers that are isolated by areas of different, perhaps nonpreferred, habitat. But even winged pollinators may be reluctant to leave a preferred habitat, such as undisturbed forest, to fly across a newly created pasture to another patch of forest. If the fragments are small enough to affect the size of pollinator populations, there may be negative genetic consequences for the smaller populations.

Modern agriculture can have a variety of negative impacts on pollinators. The creation of large fields that are disturbed regularly by plowing can prevent ground-nesting bees from establishing populations, and if only a single plant species is available there may not be enough pollen and nectar resources to support the life cycle of a pollinator species. The use of pesticides to control agricultural pests can have a negative impact on pollinators, and herbicides may remove species that could provide resources for the pollinators. Pesticide use in nonagricultural areas, such as spraying of large tracts of forest to control lepidopteran herbivores, has also been shown to have strong negative impacts on nontarget pollinator populations.

The introduction of exotic plants, such as weedy plants, could have potential implications for the pollination of native plants. If the exotics are close relatives to native species, there is the potential for hybridization. And if the exotics are prolific producers of nectar or pollen, they may draw pollinators away from native species that may then suffer a deficit in seed production. The potential for these kinds of consequences is not yet well understood, but this area is beginning to attract attention from researchers.

The ecological consequences of widespread introductions of *Apis mellifera* and *Bombus* for native plants and pollinators are not well known because of a lack of data from before the introductions. We can speculate that the introduction of honey bees to North America may have had significant consequences for species of bumble bees that have the same proboscis length, because the perennial honey bee colonies have many more workers than the annual bumble bee colonies. The spread of *Apis mellifera scutellata*, the African subspecies (“Africanized honey bees”), from its point of release in Brazil to as far north as the US was much more recent and has provided opportunity for some studies of their impact on native neotropical pollinators (relatively minor, it appears).

Species from every major group of pollinators, invertebrate and vertebrate, have been classified as endangered, and recent extinctions have been documented for others. Thus, pollinators are just as susceptible to the current human-induced mass extinction as any other group of organisms.

Potential Management Solutions

A first step in solving problems in the conservation of plant–pollinator relationships is gathering information, both about the nature of the relationships and the problems they face. Probably, the best way to conserve pollinators is to

preserve habitat that includes their food plants and nest sites. Given that the growing human population is resulting in rapid habitat destruction, the establishment of protected areas is an important conservation tool. In agricultural situations, management techniques as simple as changing the timing of pesticide application, leaving buffer zones around fields where bees can nest and food plants can grow, or providing suitable artificial nesting sites can make a significant difference. Domestication of wild bees by providing and managing nest sites may also play a role in their maintenance in agricultural situations.

If pollinators are locally extinct, it may be possible to reintroduce them once the factors that caused the original extinction are addressed. For example, a species of bumble bee that has disappeared from its native range in the UK may be reintroduced there from populations thriving in New Zealand, where the species was introduced. If the species is globally extinct, plants that were dependent on that pollinator could be maintained by hand pollination, or by the introduction of a suitable replacement. Although the bird was not introduced for that purpose, the presence of the Japanese white-eye in Hawaii has had the effect of replacing an extinct endemic avian pollinator. Another species of plant in Hawaii that lost its native pollinator is being maintained by hand pollination. Removal of introduced pollinators, such as the honey bee, may also help to preserve populations of native pollinators.

We have taken some important steps toward conservation of pollinators and thus the relationships they have with plants. But much basic knowledge about pollination and pollinators remains to be learned and it remains to be seen how many of these species can be conserved.

Glossary

Evapotranspiration The process of transferring moisture from the earth to the atmosphere by evaporation of water and transpiration from plants: actual evapotranspiration as observed at a locality or potential evapotranspiration, given unlimited water availability.

Neogene The Miocene and Pliocene Epochs, accorded the status of a period when the Tertiary is considered an era.

Physiognomy The outward appearance or morphology of a community as determined by the growth forms of the dominant plants present.

Sclerophyll A plant with tough, leathery, evergreen leaves, usually associated with drought resistance.

Sere The series of stages in an ecological succession sequence.

Temperate region Any locality with at least 1 month of frost (for continental areas) or with one or more months with a mean temperature lower than 18 °C (for maritime-influenced areas), and with at least 4 months with a mean temperature higher than 10 °C.

Tertiary The earlier part of the Cenozoic Era, occurring from about 65 to 2 million years ago.

Overview

The temperate forests are globally important and unique. They host the largest and oldest organisms in the world. They serve as the world's major source of timber and wood products and are perhaps the only forests with some proven potential for sustainable management. The biomass of at least some temperate forests stands exceeds that of any tropical forest. The temperate forests of the world also provide critical ecosystem services locally and globally. Recent evidence indicates the global importance of carbon sinks in the temperate forest zone, especially in eastern North America. On a landscape level, temperate forests are critical to modulating hydrological, nitrogen, and carbon cycles. Although the biodiversity of temperate forests is typically much lower than that of tropical forests, some temperate forests approach the biodiversity observed at larger spatial scales in the tropics. Temperate forest biodiversity hot spots with high levels of endemism rival in importance those anywhere. They have a unique evolutionary history divergent from either the tropics or the boreal regions. Moreover, Northern and Southern Hemisphere forests are as different from each other as either is from tropical or boreal forests. This contrast reflects striking differences in climate, biogeography, evolutionary history, and the impact of humans.

The objectives here are to provide an overview of the distribution of temperate forests globally; their structure and composition; evolutionary history; diversity, endemism, and rarity; ecosystems services provided; current conservation status; and current threats.

Global Distribution Patterns of Temperate Forest Systems

A global view of the forests of the world reveals everything from broad continuous expanses of trees to mosaics of small

forest patches in the landscape and from dense, closed-canopy stands to open wooded parklands. As one progresses from the equator through the humid zones at midlatitude to tree line in the polar regions, changes in forest structure and composition typically occur gradually. Demarcating where the temperate forests begin and end along this continuum is difficult. Indeed, defining "temperate" is difficult. Of the many published maps portraying the extent of the temperate forest biome, few agree on boundaries. The broadest, most arbitrary definition of temperate forests includes all forested areas north or south of the tropics of Cancer and Capricorn, respectively. More common, general macroclimatic factors have been used to define boundaries. In such cases, the results are maps of the potential distribution of forests. Because of the pervasive effects of human and natural disturbances, such maps are considerably more extensive than those depicting extant forests (compare **Figures 1** and **2**). Maps of existing forests are generally derived from remotely sensed images, but even these vary in what is portrayed as forest. In consequence, **Figure 2** does contain acknowledged, inherent errors in misclassification and omission.

Figure 1a shows where globally temperate forested landscapes may potentially be found, delimited by the humid temperate domain or ecoregion. The boundaries are based on macroclimate, which distinguishes this zone from the polar ecoregion with boreal forests, the humid tropical region with tropical forests, and the dry ecoregions dominated by arid grassland/savanna or desert vegetation. The latitudinal boundaries are set by thermal regime as modified from Köppen and Trewartha, who developed the most commonly used climate classification scheme. These zones are similar to those of Holdridge and Walter but differ in detail. The temperate region defined in **Figure 1** includes any locality with at least 1 month with frost (for continental areas) or with 1 or more months with a mean temperature lower than 18 °C (for maritime-influenced areas) and with at least 4 months with a

mean temperature higher than 10 °C. Moisture availability sets the remaining boundaries, with the humid temperate domain bounded by where precipitation equals or exceeds potential evapotranspiration. Most other maps of temperate forest biomes employ variations on this theme.

Biome or community boundaries are only approximate, reflecting the difficulty inherent in delineating features that are fuzzy spatially and temporally. Boundaries are often either broad ecotones or a mosaic of patches. Moreover, these patterns will change as the climate, biotic composition, or disturbance regimes inevitably change over time. Consequently, any map will be at best an abstract representation of reality.

Within any biome or ecoregion, subdivisions of convenience may be designated. In **Figure 1**, the humid temperate domain can be subdivided into subclimatic zones: marine (areas with temperature fluctuation moderated by oceanic influences and with elevated moisture availability, in some cases producing rainforests) and continental (areas with comparatively greater temperature fluctuation and greater probability of drought). Temperature zones are delineated as well: subtropical (defined as having 8 or more months with mean temperatures higher than 10 °C), continental hot temperate (4–7 months with temperatures higher than 10 °C, warmest month higher than 22 °C, and coldest month lower than 0 °C), and continental warm temperate (as for hot temperate, but with warmest month lower than 22 °C).

The excess of annual precipitation over evapotranspiration becomes less as one moves away from oceanic influences on

continents at midlatitudes. Thus, temperate forests tend to be replaced by grasslands in central North America, central and eastern Europe, central eastern Asia, and eastern South America. This may be augmented by fire and grazers or browsers. The boundary between forest and grassland may be a broad transitional, open wooded parkland with scattered trees, or a broad mosaic of forest and grassland patches with forests restricted to favorable soils, sites with more moisture, or sites protected from fire.

Forests may also be replaced as aridity increases in Mediterranean climates with winter rainfall–summer drought regimes. As fire becomes a pervasive element in the landscape, forests tend to be replaced by sclerophyllous shrublands, thickets, or sometimes open woodlands. Again, the transition may be abrupt or a gradual mosaic, with forest patches restricted to favorable soils and/or moist sites protected from fires.

The boundaries between the temperate forested regions and the adjacent boreal or tropical regions are often imprecise. In both cases, there can be a very broad transition zone with considerable overlap in species composition. The subtropical–tropical boundary set by the 18 °C mean monthly isocline is quite arbitrary. Some have attempted to show that this boundary approximately corresponds to the natural poleward limits of the distribution of palms.

Boreal forests are distinguished only for the Northern Hemisphere as typically conifer-dominated forests within specified climate regimes (i.e., monthly mean temperatures all

Figure 1 (a) Global distribution of the humid temperate ecoregions. These correspond to the potential distribution of temperate forest, grassland, and Mediterranean shrublands globally. (b) Representative climate diagrams for the various divisions of the humid temperate ecoregion domain (Reproduced with permission from Figure 6.2 and 6.3 in Bailey RG (1998) *Ecoregions: The Ecosystem Geography of the Oceans and Continents*. New York: Springer-Verlag.).

Figure 1 Continued

lower than 22 °C but 1–3 months with means higher than 10 °C). This boundary approximately corresponds with the mean position of the summer polar front in the Northern Hemisphere.

Confusion remains regarding the classification of conifer-dominated forests. The boreal forests of the Northern Hemisphere and the conifer forests of the North American Pacific Northwest, the Asian Pacific northeast, and the Southern Hemisphere are treated differently by different authors. Using the previously mentioned temperature criteria, all of the Southern Hemisphere forests, except perhaps the southern tip of South America, would be classified as temperate, as would most of the Pacific forests of Asia and North America. The

climatic definition for the temperate zone forests will be used here.

There are parallel inconsistencies in classifying certain subtropical forest regions. For example, northern Indian forests, which are climatically subtropical, are usually classed as tropical. The same is true for forests with some temperate affinities in subtropical regions of southern Brazil.

Dealing with mountainous areas is problematic since they typically contain multiple ecoregions (tropical or temperate to boreal and alpine depending on elevation and latitude). In the Americas, Africa, eastern Asia, and Australasia, one can find discontinuous bands of forest with temperate affinities extending from sea level in the temperate zone well into the

Figure 2 The current distribution of forests globally. The data on which this map is based were assembled by the World Conservation Monitoring Centre in collaboration with the World Wide Fund for Nature and published on the World Wide Web (<http://www.wcmc.org.uk/forest/data/wfm.htm>).

tropics at higher elevations. The most common resolution is to classify all forest elements as part of unclassified mountainous regions, as part of the surrounding domain, or as separately classified biome units within the domain. One consequence of this inconsistent classification is to obfuscate biotic patterns in some of the most important global hot spots of biodiversity.

The temperate forest biomes, thus defined, comprise about 14,600,000 ha (estimates vary). By far the largest actual or potentially forested landscapes occur in the Northern Hemisphere (80% or more) (cf. [Figure 1](#) and [Table 2](#)). The regional biomes include (i) eastern North America from the Atlantic coast west to about 95° latitude and from about 45° latitude south to about 28°; (ii) western North America from about 35° north to about 60° (and mainly from the Sierra-Cascade ranges, west); (iii) western and central Europe from the Atlantic coast north to about 60° and east through eastern Europe, but excluding the Mediterranean coastal zone and much of Spain, and then extending in a narrow strip around 55° east across Russia to west central Asia; (iv) a small, discontinuous temperate forest zone in the Middle East, especially along the south coast of the Black Sea, to the southern Caucasus and to the southern Caspian Sea; (v) eastern Asia from about 50° south to about 25° in southern China and from Japan and the Pacific coast northwest to about 120° and southwest to about 100°; and (vi) northern south Asia (India) and adjacent areas.

In the Southern Hemisphere the extent of temperate forests is much more restricted in extent: (i) eastern, coastal Australia from about 25° south to Tasmania, plus the southern tip of Western Australia; (ii) most of New Zealand; (iii) southern Chile and adjacent Argentina from about 40° south to about 55°; (iv) a small area of southern Brazil just below the tropic of Capricorn, plus adjacent Paraguay and Argentina; and (v) small patches of coastal and interior forest in south and southeastern South Africa.

[Table 1](#) summarizes the potential and current extent of forested areas within each of the 11 temperate forest biomes, from World Conservation Monitoring Centre (WCMC, see [Figure 2](#)), World Wide Fund for Nature (WWF), and the Food and Agriculture Organization data based on approximately 25 forest types. The more conservative estimate of potential forest ([Table 1](#), column 2) is for mesic forest coverage only. Maximum potential extent (column 3) includes all types of dry forest, woodlands, and thickets but not savannas or other sparsely treed landscapes (i.e., forest cover <30%). The corresponding ranges under current forest extent are shown in the fourth column. These data are only approximate. The base data were obtained from different sources, with different categories or forest type classes reported for different regions. In some cases, conflicting information on forest cover is reported from different sources.

Almost 80–90% of the temperate forest biome types are found in the Northern Hemisphere. For current forest cover, the data are only slightly less for northern dominance. The major northern forest biomes of Europe, eastern North America, and east Asia all cover about the same potential area. However, eastern North America has by far the largest cover remaining (40–45%). The Middle East has the smallest percentage of potential forest cover (13–18%), followed by east Asia (<20%) and Europe (25–30%); western North America has the highest percentage of remaining forests (60–75 + %). Estimates for western North America are only approximate (estimated from WCMC forest type information and other data), with the eastern and southern boundaries for this system fuzzy and disjunct. Similarly, the estimates for forest cover in south Asia are only approximate. For some regions these data can be deceptive. Much of the forest covering Europe, especially in western Europe, is intensively managed plantation or seminatural forest. The same is true for Japan, even though it retains more than one-third of its potential forest

Total	55.8	78.1	26.8–33.9

cover. China retains almost 12% of its original forest, but most of this is in the boreal to northernmost, mixed conifer forests.

Southern temperate forests are fragmented into six or more regional biomes, all much smaller in extent than their northern counterparts. The extreme ranges in forest cover tabulated for some of the southern biomes reflect the large contribution of dry forest systems within the regions. The largest of the southern biomes comprises the forests of southern Chile and adjacent Argentina. The smallest of all temperate forest biomes is that found in South Africa, perhaps rivaled in size only by the forests of Western Australia. Most significantly, the South African forests are the richest of all temperate forests in tree families, genera, and possibly species (certainly if the complete tree flora is included).

Compared to other forest system globally, the temperate forest biomes covers a slightly greater area than boreal forests. Boreal and temperate forests together approximate the tropical forests of the world (Table 2).

General Characterization of Temperate Forests

Physiognomic Features

Each of the previously discussed 11 temperate forest regions may be characterized by general physiognomic features (i.e., the outward appearance and structure of the dominant vegetation):

1. Eastern North America: dominated by broadleaf deciduous forests, mixed with conifers to the north, locally dominated by conifers under drier, successional conditions or in fire-prone areas in the southeast and northwest, plus small patches of broadleaf evergreen forests in the south. Closed forest systems predominate.
2. Western North America: dominated by evergreen conifers with broadleaf trees contributing little to the forests; some northwestern coastal areas support rainforests (i.e., rainfall in excess of 2000–3000 mm per annum). The eastern edge of this biome is discontinuous and grades to open conifer woodlands and montane boreal forests. To the south it grades to a mosaic of conifer or broad-leaved evergreen forests and woodlands or shrublands.
3. Europe: mainly broadleaf deciduous forests, mixed with conifers to the north and in mountainous areas, and to the south grading to a mosaic of broadleaf evergreen forests (many sclerophyllous leaved), conifer-dominated

forests, and shrublands under Mediterranean climate influence.

4. Middle East: mainly broadleaf deciduous forests with a mosaic of broadleaf evergreen, sclerophyllous, and conifer forests and woodlands. Rainforests occur very locally near the southeastern Black Sea coast.
5. Eastern Asia: mainly broadleaf deciduous forests mixed with conifers to the north and broadleaf evergreen forests to the south; mostly mesic closed forests. Evergreen broad-leaved rainforests occur locally in southeastern Japan, one of the rarest forest types found in the Northern Hemisphere.
6. South Asia: dominated by broad-leaved evergreen to semievergreen monsoonal forests; temperate mixed forests (locally rainforests) occur in the foothills of the Himalayas.
7. Australia: dominated by broadleaf evergreen forests (mostly sclerophyllous); small patches of closed forest (<70% cover) and extensive areas of open forests grading to woodlands. Very restricted patches of rainforest are found in southeastern Australia and western Tasmania.
8. New Zealand: dominated by conifers and mixed with broadleaf evergreen forest patches, especially on the north island and locally on the south island. The western forests in New Zealand are rainforests.
9. Southern South America: dominated by broadleaf evergreen forests with some conifers. Broadleaf deciduous forests prevail in the southernmost areas and at higher elevation in the Andes; rainforests are restricted to the Pacific slope south of about 40° latitude.
10. Southern Brazil: characterized by the presence of southern conifer forests; elsewhere in this zone the forests are dominated by evergreen or semideciduous angiosperms with patches of open forest and thicket to the west.
11. South Africa: mixed broadleaf evergreen (many sclerophyllous leaved) with some conifers forming a very patchy mosaic in the landscape with thickets, shrublands, and savannas.

Dominant Floristic Features

The community dominance and floristic affinities for these regions as they exist today can be characterized very broadly. Detailed descriptions and characterizations may be found elsewhere. There are broad floristic affinities among the forested biomes in the Northern Hemisphere with many shared

families and genera both now and in the fossil record. These include older lineages from the Tertiary flora of Asia and recent lineages that evolved under cooler and/or drier climates. The Southern Hemisphere forests are very different floristically, with few important families or genera shared with the north. There are some Gondwanan lineages in common now or in the fossil record. However, the floras today reflect considerable divergence with many tropical affinities and many fewer common links than are seen in the north.

In eastern North America, in the northeast birch, maple, beech, and hemlock (*Betula*, *Acer*, *Fagus*, and *Tsuga*) dominate the landscape, with the latter two tending to form monodominant stands late in succession. Farther south and west the forests tend to be dominated by oaks (*Quercus* spp.) or hickories (*Carya* spp.). The central sections, especially in the central to southern Appalachians, tend to be the richest, with a diminished tendency toward dominance by one or a few canopy species, although the highest regional tree diversity is found in the southeast. In the extreme south, small patches of evergreen forest are found in protected areas dominated by evergreen oaks and *Magnolia*. Much of the southeast is now dominated by pine (*Pinus taeda*) plantations. Fire successional pines also dominate parts of the northwest. Drier sites throughout tend to be dominated by oaks or conifers, especially pines; wetter sites are dominated by conifers (e.g., *Tsuga* to the north and *Taxodium* to the south) or by locally adapted broad-leaved deciduous species (e.g., *Ulmus*, *Nyssa*, and *Acer*).

Western North American forests are dominated by a small number of large, long-lived conifer species; deciduous angiosperms are only minor components. The Pacific Coast rainforests are dominated by hemlocks (*Tsuga*), firs (*Abies*), spruce (*Picea*), and/or cedar (*Thuja*) from Alaska south to Washington State. Douglas fir (*Pseudotsuga*) becomes important in the central coast. Timber industries in these zones tend to actively manage the landscape for monospecific stands of native species (e.g., Douglas fir). Fragmented stands of redwoods (*Sequoia*), which globally are the tallest trees, occur more southerly extending to central California. On the drier eastern slopes of the coastal mountains (central sections), pines, Douglas fir, and sometimes poplars (*Populus*) dominate the landscape. Further south in the Sierras one finds local dominance by *Sequoiadendron*, the most massive tree globally, and *Pinus aristata*, the longest lived tree. Drier, lower elevation landscapes in the south (California) may be dominated by broad-leaved evergreen forests of tanoaks (*Lithocarpus*) and madrone (*Arbutus*) or open oak, pine, or mixed woodlands, which grade into Mediterranean shrublands or grasslands.

European forests are highly disturbed and fragmented following centuries of human habitation. Central European forests tend to be dominated by beech (*Fagus*) on many intermediate sites and by various oaks (*Quercus*) on drier and slightly wetter sites or very acidic sites. The wettest sites tend to be dominated by birches (*Betula*). Many of these forests have been converted to *Picea* or *Pinus* plantations. For example, German forests have gone from 90% deciduous broadleaf domination to 80% *Picea* plantations. To the south there is a transition to dominance by evergreen oaks and pines under Mediterranean influence. To the north and throughout much of the central uplands, conifers (*Pinus*, *Picea*, *Abies*, and *Larix*) can locally dominate the landscape or there are mixed forests

with beech and birch. Many of the European forests not in plantation are still actively managed for timber products.

The Middle Eastern forests of northern Turkey to the Caucasus and the southern Caspian Sea are probably the poorest known and least studied of temperate forests. In the western Mediterranean-influenced zone, one finds sclerophyllous forests and woodlands dominated by pines and oaks. Along the coast of the Black and Caspian Seas and the southern Caucasus (Colchian and Hyrcanian regions) one finds highly diverse, mesic deciduous forests with oaks, maples, beech, chestnut, and many other species. At higher elevations the forests are dominated by beech with conifer-dominated or mixed stands above. Drier sites in the landscape are dominated by open oak forests or woodlands. Many of these forests have experienced a long history of human occupation and associated agriculture with overgrazing.

East Asia has the most diverse forests in the Northern Hemisphere. Along the Pacific coast in northern Japan, southern Russia, and China, one finds forests similar to those of the North American Pacific Northwest, with conifer dominance but also mixed with broad-leaved species of maples, birches, limes (*Tilia*), and elms. Central China has been extensively cultivated for centuries, and there is very little forest cover left. Remnant tracts here indicate a rich diversity of mixed deciduous trees mentioned previously plus many other genera, including oaks, elms, poplars, ash (*Fraxinus*), and rowan (*Sorbus*), with a rich understory. Locally, the understory may be dominated by bamboos. The same pattern is seen in Korea and Japan. In southern Japan, much of the forest is managed for native *Cryptomeria*, and in the north it is managed for *Abies* or *Picea*. South of the Yangtze River in China and in eastern and southern Japan the broad-leaved evergreen species increase in dominance as one approaches subtropics. These are the most diverse temperate forests in the Northern Hemisphere, with many of the same genera listed previously. However, these have become highly fragmented through human disturbance. In southern China there is a shift to forests with strong tropical affinities.

The temperate forests of south Asia are difficult to categorize. Most of the lowland and premontane remnant forests of northern India are climatically subtropical but the flora has strong tropical affinities. There is local strong dominance by Sal (*Shorea robusta*) and bamboos. In the northern hill forests there is a transition to strong temperate affinities with high species diversity. Oaks mixed with Lauraceae dominate the forest, but maples, *Castanopsis*, and *Magnolia* occur. In the montane zone diverse oak forests are mixed with conifer (*Abies*, *Picea*, and *Pinus*) forests and patches of *Rhododendron*. As is the case in much of Asia, these forests have been long affected by human disturbance. Throughout the lower elevations small stands of *Eucalyptus*, teak, pine, or *Populus* plantations are common.

The subtropical forests of the eastern mountains and coastal areas of Australia and the small areas of forest in Western Australia are dominated by the numerous sclerophyllous *Eucalyptus* species. Locally, stands tend to be dominated by one or only a few species. The eucalypt forests tend to form open-canopy stands grading to woodlands. The tallest angiosperm trees are found here. Only on Tasmania and in scattered pockets along the eastern mountain chain is there

Table 3 Tree species diversity patterns across the temperate forested region

Region	Families	Genera	Species	Genus:family	Species:genus	Forest biome maximum extent (km ² × 10 ³)
Europe	21	43	124	2.0	2.9	3300–3910
East Asia	67	177	876	2.6	4.9	3210–3790
Eastern North America	46	90	253	2.0	2.8	3560–3720
Western (Pacific) North America	24	47	131	2.0	2.8	700–1000
Chile	29	40	83	1.4	2.1	330–370
Southern Brazil	25	45	77	1.8	1.7	< 100
Southeast Australia	37	78	331	2.1	4.2	300–700
New Zealand	47	74	212	1.6	2.9	230–250
Southeast South Africa	88	280	598	3.2	2.1	20–50

local dominance by closed-canopy or temperate rainforest species, including the southern beech (*Nothofagus*) and various southern conifers (*Dacrydium*, *Phyllocladus*, *Arthrotaxus*, or *Araucaria*). Throughout much of southeastern Australia plantations of Monterey pine (*P. radiata*) have become a pervasive component of the landscape.

The forests of New Zealand tend to be either multi-storied mixed conifer–broadleaf with species composition varying across the landscape or low-diversity southern beech (*Nothofagus*) forests. The mixed forests dominating in the lowlands have a scattered overstory of *Agathis* in the north or various podocarps (e.g., *Podocarpus*, *Dacrycarpus*, and *Phyllocladus*), with a sub-canopy of Lauraceae (*Beilschmeidia*), Myrtaceae (*Metrosideros*), Cunoniaceae (*Weinmannia*), and many other families and genera. Evergreen *Nothofagus* forests may form pure dense canopies in subalpine areas and may be a component in the lowland forests along with other broad-leaved species.

The forests of southern South America are confined to Chile and adjacent areas of Argentina. They vary from small remnants of sclerophyllous forests and woodlands in the Mediterranean zone to the species-rich Valdivian rainforests, the species-poor but still extensive north Patagonian and Magellanic forests, and depauperate deciduous *Nothofagus* forests at higher elevations and the interior south. The sclerophyll forests were dominated by *Acacia caven* and other species, with deciduous *Nothofagus* forests at high elevation. The Valdivian forests may be either broadleaf dominated, with *Nothofagus*, *Eucryphia* (Eucryphiaceae), *Laurelia* (Monimaceae), *Weinmannia*, and other species, or mixed with conifers (*Podocarpus*, *Araucaria*, or *Fitzroya* (Cupressaceae)). The north Patagonian/Magellanic forests are dominated by evergreen *Nothofagus* mixed with *Podocarpus*, *Weinmannia*, and *Drimys* (Winteraceae). To the south, one of the deciduous *Nothofagus* species (*N. pumilo*) forms a pure stand or is mixed with *N. betuloides* at timberline. Many of the remaining Chilean forests are being clear-cut for chips and converted to *P. radiata* or *Eucalyptus* plantations.

The southeastern forests of Brazil have many south temperate affinities. These forests are characterized by the presence of *Araucaria*. However, other south temperate components include *Podocarpus*, *Weinmannia*, and *Drimys*, plus Sapindaceae, Proteaceae, and Myrtaceae. These forests have been largely cleared

for agriculture. The subtropical forests to the west in adjacent Paraguay and Argentina have more tropical affinities.

The forests of South Africa are some of the richest in tree species of any in the temperate zone. However, this is also the smallest of all temperate forest biomes, and it is highly fragmented into many small forest patches. It is not clear how forest cover has changed during the Pleistocene. These forests do have south temperate affinities, with the presence of *Podocarpus*, Cunoniaceae, and Proteaceae, but the majority of the temperate forest flora have tropical affinities. Despite these tropical affinities, the level of tree endemism is high for a continental area contiguous with tropical forests. The “Afro-montane” forest elements extend from southernmost South Africa at sea level to the mountains through north-eastern Africa. The coastal, Indian Ocean (Maputaland/Pondoland) forests are quite different floristically, with high diversity and many local endemics. The vast majority of the forested landscape is now in *P. radiata* or *Eucalyptus* plantation.

Trends in Biodiversity

Comparing trends in biodiversity within and among regions is fraught with difficulties. The results can differ depending on the scale of the sample unit compared (i.e., 0.001 vs 1, 1000, or 100,000,000 ha). For many regions of the world, data are available only for a limited scale range. For example, in east Asia there are very few accessible data records for small plots (0.1–100 ha). In other regions (e.g., the Middle East), species diversity numbers are either estimates for large areas or entirely lacking. For many records the number of tree species may be accurately reported but the number of herbaceous, especially ephemeral, plants may be significantly undercounted or not reported at all. Even simply listing tree species numbers can be misleading because authors vary widely in delimiting the threshold size for what constitutes a tree. Likewise, authors vary in classifying vegetation type with which tree taxa may be associated (closed forest to sparsely treed parkland). Nevertheless, some trends appear robust.

Table 3 summarizes regional tree taxon richness from a variety of different sources, and **Figure 3** plots tree richness tallies against area for 75 forest sample sites throughout the temperate zone (spanning 10⁻² to 10⁸ ha). Despite this large

Figure 3 The relationship between tree species numbers and area sampled is shown, log transformed for both variables. The samples are from a wide range of different sources for most of the temperate zone forest biomes. These are simply classified here as Northern (n) and Southern (s) Hemisphere localities with best fit linear regression lines. There were significant differences between hemispheres ($p=0.024$, $n=75$, $r^2=0.695$) and among regions ($p<0.001$, $r^2=0.916$).

range in areas and the inherent variation in estimates and counts, there are significant differences in tree richness among biomes and between hemispheres. For these data, greater tree species richness occurs in the Southern Hemisphere across the full range of areas surveyed (Figure 3). This is also reflected in the absolute number of families and genera. For species, the totals are similar, but the tabulated survey covers only a small part of the diverse tree flora for Australia and South Africa, respectively, and only part of southeastern Australia and Tasmania and Kwazulu-Natal province and adjacent Transkei. If all the tree species are included for South Africa alone (well over 1000 species in 370 genera and 97 families), the species numbers would be higher in the Southern Hemisphere despite the fact that southern forests only cover 10–20% of the area of northern forests. On an area basis, the taxon richness of the southern forests is at least an order of magnitude greater than that of the north.

This high southern diversity is contributed largely by the flora of South Africa, arguably one of the richest per unit area of any biome globally. Australia and New Zealand also contribute to this southern richness, each having a taxon richness per unit area of 4–10 or even 100 times that of northern forested regions. Just the rainforests of New South Wales and Victoria, covering less than 200,000 ha, have more than 250 tree species (not all included in Table 3). Even the Chilean forests, perhaps the most depauperate in tree species of any temperate forest biome, have more taxa per unit area than any northern biome (except for total species in east Asia).

Among northern temperate forest biomes, east Asia has by far the richest tree flora. Europe and western North America are the most depauperate, with Europe having the lowest tree taxon diversity per unit area globally.

Figure 4 The relationship between total vascular plant diversity and area samples is shown, log transformed for both variables. The samples are from a variety of different sources covering most of the temperate zone forest biomes. The samples are classified by the biome region from which they were obtained. Significant differences are found between hemispheres ($p=0.005$, $r^2=0.924$, $n=198$) and among regions ($p<0.001$, $r^2=0.938$).

Figure 4 shows analogous species area data for all vascular plants tallied for about 200 plots or regions (spanning 10^{-6} to 10^8 ha) across all temperate forest biomes. Here, the hemisphere trends are reversed. The north has a slight but significantly higher total vascular flora than the south across the range of sample areas. East Asia and the Middle East (the latter, a smaller sample size) tend to have the highest vascular plant diversity, and New Zealand, South America, and western North American forests tend to have the lowest vascular plant diversities. Forested systems in eastern North America, Europe, Australia, and South Africa tend to be intermediate across areas sampled. There is a dramatic decrease in species diversity toward the pole, more so in the Southern Hemisphere. In pairwise comparisons at intermediate sample areas the trends tend to hold. The vascular plant flora for east Asia at 0.5–10 ha is significantly richer than that of Europe or eastern North America. However, few differences can be seen among regions at the smallest plot sizes (<0.01 ha).

Trends in alpha, beta, and gamma diversity vary considerably within and among regions. Some of the large- to intermediate-scale patterns in species richness are undoubtedly related to spatial landscape heterogeneity. Regionally, high levels of species richness are associated with mountains (e.g., the Smoky Mountains (east North America), the Pyrenees, Alps, or Balkan Mountains (Europe), and the Sichuan Mountains or Mount Halla (east Asia)). Complex mosaics of vegetation types (e.g., southeast Australia or Pondoland (South Africa)) or multiple successional states (e.g., Indiana Dunes National Seashore) all tend to support significantly higher diversity than adjoining areas. Even for the United Kingdom, with an exceptionally small flora overall, regional or county floras that encompass a diversity of habitats and seral stages may have as many species as are found in many similar-sized temperate regions elsewhere. Within Europe there many more tree species in the southern,

Mediterranean-influenced region with complex spatial heterogeneity (almost 100 versus 12 common and 25 uncommon species in northern and central Europe). Perhaps the high tree and overall species diversity in South Africa is related to the extreme spatial heterogeneous and natural fragmentation of the vegetation (forest and otherwise). Locally or regionally, lower species diversity tends to be found under closed conifer forests and late successional stands dominated by trees that cast deep shade. Often, the highest diversity will be found in intermediate successional stage forests or in a landscape with a mosaic of seral stages. Locally, higher diversity will tend to be found on richer, fine-textured soils with circum neutral pH with higher cation exchange capacity and more humus. This contrasts with diversity trends elsewhere. For example, higher diversity tends to be found on poorer soils in Mediterranean shrubland biomes.

Compared to tropical forests, the species richness (of trees or all vascular plants) in the temperate zone will usually be smaller than that of comparable areas in the tropics, especially at the 0.05- to 10-ha scale. Most temperate forest stands tend to be dominated by one or a few species, with the other tree species being uncommon or rare. In the majority of tropical forest stands local dominance by one or a few species is rare; greater evenness is common. Perhaps only on a regional basis may floristic diversity of temperate forests (e.g., southern China and South Africa) begin to approach those observed in the tropics.

An alternative measure of global richness patterns may be obtained by focusing on clades or higher taxonomic richness. The data from [Table 3](#) show more genera and families in the Southern Hemisphere forests sampled. Also, the ratios of species to genus and genus to family tend to be lower in the south. These trends indicate a potentially richer phylogenetic diversity (using higher taxa in lieu of cladistic information) in the south. A complementary, global perspective is provided by the British Natural History Museum (NHM) global mapping of plant family richness (395 in total) on 10° latitude/longitude grids. The trends reveal higher family diversity on average in the tropics, with the richest cell in Southeast Asia, and a dramatic decline poleward. However, family richness is as high in southern China as it is anywhere else in the world (other than Southeast Asia), and about as high in the central southern United States as in most of South America (including Amazonia) and southern Africa versus tropical Africa. Centers of plant family richness in the temperate zone at the 10° grid cell included southern east Asia, southern North America, and southern Africa, with lower diversity in Europe and temperate Australia and South America.

Endemism and Range Size Rarity

Endemism (species restricted to specific localities) and taxon rarity have received a similar amount of attention as has biodiversity. How do levels of plant endemism compare among temperate forested regions and with other biomes? Statistics on plant endemism tend to be available for only a limited range of spatial scales (often countywide, occasionally for states or provinces, and infrequently for localities) and are often incomplete or lacking for poorly known regions such as

the tropics. Nevertheless, there are some trends in the data that are available. Boreal and cold temperate forested regions in the Northern Hemisphere tend to have very low levels of endemism based either on absolute numbers or the percentage expected on average per unit area (e.g., northern and western European countries (0–2%) and the eastern United States (0 to <1%)). Regions that include warm temperate to subtropical regions with topographically heterogeneous landscapes (and therefore heterogeneous climates and vegetation types), and especially with isolated mountain ranges, tend to have higher than expected endemism per unit area (e.g., Bulgaria (9%), Turkey (31%), western North America, and countrywide for China (56%)). Larger islands and peninsulas tend to have higher than expected species diversity (e.g., Korea (14%), Florida (12%), Japan (37%), and New Zealand (82%)). The Southern Hemisphere forested regions tend to have some of the highest levels of floristic endemism globally (50–80% for Australia, New Zealand, Chile, and South Africa). In part this reflects their geographic isolation. The previous data are for species endemism for the entire flora. Tree species endemism is more difficult to determine and likely to be much lower. For example, in South Africa about 25% of the more than 1000 tree species are confined approximately to the borders (and enclaves) of the country and about 40% to southern Africa (versus 70–80% for the entire flora). Regional tree endemism is much lower (e.g., about 8% for Pondoland and 15% for Maputaland forest regions). However, very high levels of tree species continental endemism are found in southern South America: 85% of woody species and 34% of genera are endemic.

Compared to tropical forests, the absolute numbers of endemics are generally lower in the temperate zone, except perhaps for some of the Southern Hemisphere temperate zone. This reflects the larger floras in the tropics, which are still poorly known for many localities. However, on the basis of expected percentage endemism per unit area the trends are less clear. For example, although Venezuela (38%), Panama (13%), and the Congo (29%) have higher than expected levels of plant endemism, Columbia (4%), Nicaragua (<1%), and Nigeria (4%) have lower than expected endemism. On a subregion or local basis the tropics may well have substantially higher levels of endemism than equivalent localities in the temperate zone, but this pattern remains to be shown conclusively.

Species endemism is only one way to assess rarity or the geographical restrictions of taxa for conservation purposes. Range size rarity of taxa or clades evaluated in the absence of political or other arbitrary boundaries may be a more consistent and robust means of judging rarity. A global survey by the British NHM of range size rarity was done on a 10° grid for selected plant taxa. This showed that there were no clear trends between warm temperate and tropical regions in range size rarity. Many, perhaps the majority of the prime hot spots, are in temperate grids that include forested regions (e.g., southern South Africa, central China, southeastern Australia, and central to south-central Chile, with secondary centers in southern Chile, northern New Zealand, elsewhere in China, and the southeastern United States). Clade rarity and endemism need evaluation as an alternative to enumerating species endemism or range size rarity.

Explanations for Patterns of Diversity and Endemism

A variety of hypotheses have been put forward to explain local and global patterns of species distributions and therefore richness. One author lists as many as 120 named hypotheses for variation in species richness. Geological and biogeographic history provides one set of important related explanations for observed trends in richness and endemism. This may well explain some of the patterns within and between hemispheres.

Historical and Geological Explanations

In the Triassic period global plate tectonic activity had united major landmasses of the world to form a single supercontinent (**Figure 5**) which created the potential for a common biota. However, by the beginning of the Cretaceous this landmass began to break up, forming northern and southern landmasses. This, together with the formation of a broad sea, effectively isolated the northern Asiamerica continent from the southern Gondwanaland. The angiosperm and gymnosperm floras on these separate landmasses thus began to evolve independently. This history is reflected in both the Tertiary floras of the fossil record and the floras we see today. Until approximately 40 million years into the Tertiary the climate was warm, moist, and relatively stable. In the Northern Hemisphere forests spanned North America and Eurasia into the present-day Arctic. In the mid-Cretaceous (100 million years ago (mya)) these forests were dominated by both conifers (Pinaceae, Ginkgoaceae, and Taxodiaceae) and angiosperm taxa. Early examples of widespread flowering plant genera include *Magnolia*, *Betula*, and *Platanus*. Many modern northern genera soon followed in the fossil record (e.g., *Quercus*, *Castanea*, *Carya*, *Ulmus*, *Juglans*, and *Acer*), also spanning the Northern Hemisphere.

By the beginning of the Neogene, approximately 25 mya, the climate began to change, becoming cooler and drier in certain regions as a consequence of mountain building and shifts in ocean currents. In the cold northern regions, conifers were favored, giving rise to the boreal forests. At midlatitude, summer drought and/or winter cold favored deciduous angiosperms. Midcontinent aridity also gave rise to the temperate steppe grasslands and deserts. This, together with Pleistocene glaciation, undoubtedly contributed to divergence in the north temperate forest floras and their biodiversity.

In Europe and central Asia, east–west trending mountain ranges and arid zones blocked the southward retreat of the forests as the glaciers advanced. In consequence, there was apparently greater species extinction here than elsewhere in the Northern Hemisphere, and geographic isolation prevented recolonization from temperate or tropical locations elsewhere. In contrast, in east Asia, continental glaciation was less extensive and continuous connections with tropical wet forests permitted temperate forest species to retreat south and advance north with climate oscillations; there were many fewer extinctions and thus greater retention of an older phylogenetic diversity. This tropical connection undoubtedly accounts for the greater tropical affinities seen in the flora of east Asia today. In eastern North America the mountains trend north–south and thus migrations with the glacial oscillations

were possible. However, the tropical connections were largely blocked by seas or arid zones. Compared to Asia, there were more extinctions with fewer opportunities for recolonizations by taxa with tropical affinities. In eastern North America the phylogenetic lineages have a more recent and more northerly balance. Western North America suffered the greatest extinctions. Extensive mountain building, accompanying aridity, and the development of a Mediterranean climate to the south favored conifers or sclerophyllous trees with divergent evolutionary lineages from those of the mesic Tertiary forests. To the north, cool, wet climates favored conifer forests (many with tertiary affinities) at the expense of angiosperms.

The forests of the Southern Hemisphere began similarly in the Cretaceous. Warm, mesic, mixed conifer and angiosperm forests spanned Gondwanaland. These were dominated by southern conifers, including Auracariaceae and Podocarpaceae, and southern angiosperms, including Cunonaceae, Proteaceae, Myrtaceae, and Sapindaceae. In addition to these, Casurinaceae and the genus *Nothofagus* were present throughout, except on what became Africa. Gondwanaland began to break up early in the Cretaceous (**Figure 5**) well before Asiamerica. Southern Africa and India had become isolated by the early Cretaceous. This undoubtedly accounts for Africa's greater dissimilarity with the rest of the southern temperate flora. India eventually joined Asia and today it has primarily north temperate or Asian tropical floristic affinities. Not until early in the Tertiary did South America, Antarctica, and Australia finally separate. Climate changes in the Southern Hemisphere were less dramatic during the Neogene and Pleistocene than they were in the north. Aridity and glaciation were more localized; the climate remained less continental. In consequence, the forest flora retains more characteristics of the warm, mesic Tertiary flora than is the case in the north.

During the Neogene, temperate southern Africa experienced increased aridity. With climatic oscillations the forests expanded and contracted. Many of the Gondwanan elements became extinct, leaving only a couple of species of Podocarpaceae and a minor contribution of Cunonaceae and Proteaceae to the forest flora today. Connections along the east coast of southern Africa allowed connections with the tropical forest flora, and today the temperate South African forests have the strongest tropical affinities of any temperate region and the greatest tree diversity. Exceptionally high levels of spatial and temporal environmental heterogeneity may contribute to speciation here as well. With substantial tropical affinities also found in Australia and New Zealand, the southern forests as a group have a much stronger representation of tropical plant families than do the northern forests.

During the Pliocene the southern temperate forest region of Chile and adjacent Argentina became isolated from the rest of South America by the Andes and arid zones to the north and east. The isolation and relatively small extent of these forests undoubtedly account for the low diversity and high endemism found here. Only in the extreme south of Chile and at high elevations with lower mean and absolute temperatures are deciduous (*Nothofagus*) forests found in the Southern Hemisphere.

Australia and New Zealand retain much of their Tertiary flora. The maritime climate of New Zealand has changed relatively little during the Tertiary. Its long isolation from other

Figure 5 Changes in the locations of continental landmasses are shown from the Mesozoic to the early Tertiary in Lambert equal area projections. Areas on the back projection of the spheres are folded out for view. Dashed lines indicate shoreline of modern continents, hatched areas are epicontinental seas, and stippled areas are oceans. Reproduced from Cox CB and Moore PD (1985) *Biogeography*. Oxford: Blackwell, with permission from Wiley.

landmasses is responsible for the high level of endemism. Increased aridity in Australia in the Neogene substantially affected the temperate forest structure and composition. Explosive radiation occurred in the genus *Eucalyptus* (Myrtaceae) and *Acacia* (Mimosaceae). Unique among temperate forests, there are more than 500 species of *Eucalyptus* in Australia (many restricted to temperate forests). These are sclerophyllous-, drought-, and fire-tolerant tree species that dominate most of the temperate forest and woodlands in the east and west. Only in moist, cool patches in the southeast or at higher elevations are remnants of the tertiary flora found. *Nothofagus*, *Araucariaceae*, *Podocarpaceae*, and other groups are part of the rich tree flora.

The previous account indicates that it is not simply history or geology but a complex process that incorporates the role of temporal and spatial heterogeneity, geographic isolation, recent Pleistocene effects, and the role of climate stability that jointly affect the patterns of taxon distributions, diversity, and endemism we see today. What about other explanatory variables?

Productivity

The differential effects of solar radiation figure prominently as an explanatory hypothesis, measured either directly or indirectly via actual or potential evapotranspiration (i.e., AET or PET) or productivity. There is conflicting evidence on the relative importance of this as an explanatory variable versus historical factors, at least at the regional scale. Examined at the plot level (~ 1 ha) across regions, correlations are found between diversity and AET. There are also correlations at the regional and latitudinal scales (boreal vs temperate vs tropical forests). However, other evidence shows that differences at regional and local scales can be well explained by historical factors after taking into account AET. Global joint correlations between species richness and productivity were examined by the British NHM for plant family diversity on a 10° grid scale. This study showed higher family richness than expected from productivity in southern Africa, southern North America, and southern east Asia and lower or expected diversity elsewhere in the temperate zone. Undoubtedly both sets of factors may be involved, but these remain only correlates; cause–effect relationships have not been demonstrated.

Spatiotemporal Heterogeneity and Other Explanations

The roles of disturbance regimes and environmental or habitat heterogeneity at local and regional levels have figured prominently as explanatory hypotheses for richness patterns. Higher diversity is predicted under intermediate levels of disturbance. On a local or landscape level there is considerable evidence to support this idea. Midsuccessional forests and successional diverse landscape support a richer flora. For example, in northeastern North America many of the extinct or threatened species are those that occurred in open or early successional landscapes that were common 100 years ago but have since disappeared with the homogenizing reforestation of the landscape.

The predominant natural disturbances in temperate forest zones include fire and windstorm. Fires are most prevalent in the drier forests of western North America, Australia, South Africa, and the Mediterranean Basin. In many of these systems, periodic fires contribute to higher landscape biodiversity. The role of fires in other forest systems is less clear. Large cyclonic storms affect mainly eastern coastal, midlatitude regions in the Northern Hemisphere (eastern North America and Asia). Tornadoic events are most prevalent in midcontinental North America. Such storms contribute to heterogeneous successional stages in the landscape and thus higher diversity. Occasionally, human activity can contribute to higher landscape diversity. Historically, Europeans husbanding the landscape for diverse forest products undoubtedly increased the local diversity over what it would have been naturally. Humans creating a moderate spatially and temporally heterogeneous landscape ironically may contribute slightly to increased regional diversity. The higher regional species richness in mountainous areas associated with the manifold habitats was discussed previously. Another example is the extremely rich South African forests (and other biomes). The high local and regional richness has been largely attributed to the environmental heterogeneity found at this scale.

In addition, there are many other explanatory variables for patterns in species richness, some of which were intimated or included in the topics discussed previously: environmental stability or predictability, abiotic rarification, land area, seasonality, aridity, range limits and geometric constraints, and many more. For many of these factors it is easy to establish correlation and much more difficult to establish cause–effect relationships.

Ecosystem Services

Temperate forests provide important ecosystem services globally, regionally, and locally. Temperate forests contribute about 17% to global net primary productivity (versus about 49% for tropical forest systems and 8% for boreal forests). However, recent evidence from atmospheric and oceanic CO_2 data point to temperate forests, especially those in eastern North America, as globally important carbon sinks. The magnitude and causes of the net carbon uptake by temperate biomes are uncertain. However, it may be related to the reforestation that has occurred during the past century, especially in North America. CO_2 fertilization, anthropogenic N deposition, and global warming may contribute as well.

At local to landscape levels there are tight links among forest structure, composition, and species richness; soil attributes; mineral and hydrological cycles; and human disturbances. In the moist temperate zone species richness tends to be higher on soils that are better drained, warmer, and finer textured, with greater $\text{NO}_3\text{--N}$ and P availability and higher cation saturation and lower Al^+ (toxic) levels, all associated with higher pH. These attributes are associated with many calcareous soils. Thinner calcareous soils, which apparently create greater spatial heterogeneity in forest canopies, are also associated with higher local richness. Hence, soil attributes are intimately related to pattern in species diversity. The extent to which these features are altered will directly affect biodiversity;

the extent to which the community structure and composition are changed will feed back on these variables.

The strongest correlates of productivity tend to be soil texture and N cycling, which in turn are correlated with moisture retention, cation exchange, and maximum levels of humus accumulation. These correlations are strongest in undisturbed forests. Also, ecosystem control by soil texture extends over long time frames. Human disturbances can profoundly affect these links. Soil compaction with intensive forest management will have a cascading and long-term effect on nutrient and hydrological cycles. As the studies at Hubbard Brook Experimental Forest have demonstrated, forest clearing will dramatically alter watershed hydrology (increased water loss and sediment loss), nutrient cycling (with elevated nutrient loss), microclimate, and species composition for years or decades. Changes in forest species composition such as with conifer plantations will have an equally large effect. Substituting homogeneous conifers stands for mixed broad-leaved forests will increase C/N and lignin/C ratios, which in turn reduces decomposition rates, N mineralization rates, and pH, with cascading effects on cation exchange capacity and diversity in the soil flora and fauna. For example, in German *Picea* plantations, N cycling between canopy and forest soils is reduced by 75% from that observed in native beech forests. Moreover, with greater stem interception of precipitation, the conifer forest soils also become drier. In consequence, it may not be possible to successively reintroduce beech forests on these sites without large-scale soil amendments.

Even small changes in the broadleaf forest composition can alter decomposition rates and nutrient status. For example, sugar maple (*Acer saccharum*) and ash (*Fraxinus*) promote higher N mineralization, and sugar maple accumulates calcium. In contrast, oak-dominated forests have lower N mineralization. Substituting exotic species in plantations can dramatically alter ecosystem processes. *Eucalyptus* and *Melaleuca* tend to significantly lower water tables where they have been introduced. In the northeastern United States, Japanese barberry (*Berberis thunbergii*) has become a seriously invasive exotic, forming a continuous shrub layer. Under barberry canopies soil ammonium N levels are elevated, the soil flora and fauna are altered, and native species richness is depressed.

Conservation Status

Table 1 shows the approximate extent of protected forests in each of the regional biomes based on WCMC global data for International Union for the Conservation of Nature (IUCN) conservation protection categories I–VI. Globally for temperate forests, 6 or 7% of the remaining forests receive some level of protection. This represents about 1 or 2% of the total temperate forest biome extent. Compared to other forest systems, temperate forests are slightly better protected than boreal forests (6 or 7% versus 5 or 6%) but apparently less well protected than tropical forests as a whole (10–12%).

There is considerable variation both within and among regions in the level of forest protection as well as among forest types. For example, temperate freshwater swamp forests are afforded the least protection (2.7% globally), whereas Southern Hemisphere evergreen broadleaf forests receive the

highest level of protection (22.6% globally). Overall, Southern Hemisphere forests are afforded significantly better protection as a group than are northern forests.

The level of protection varies considerably among regions and countries within the temperate zone: Less than 3% of east Asian temperate forests are protected, but this varies with forest type from about 5% for cool to cold temperate and subtropical forests to 1% or less for most warm to hot temperate forests types (except for warm temperate rainforests, which only cover a tiny area and are about 15% protected). There is considerable variation among the countries of east Asia in the amount of forest afforded protection: almost 10% for Japan to less than 5% of China and less than 1% of North Korea. For Europe (excluding Russia) about 8% for the various forest types are given some protection. This also varies considerably among countries: As much as 25% of the broad-leaved deciduous forests in Germany are protected, whereas <1% in Bosnia and 2% in Russia are protected. For North America, the extent of forest protection varies from about 15% for conifer-dominated temperate rainforests to 7% for the northern cool or cold temperate forests and about 2% for the warm to hot temperate and subtropical forests versus more than 9% for North American boreal forests. The forests of the Middle East, which are the most reduced in extent, are afforded the least protection over all. Less than 3% of the forests are protected in this zone. This varies from <1% in Georgia and Azerbaijan to 1% in Turkey and perhaps as much as 12% in Iran. About 8% of India's temperate forests have some level of conservation protection. For temperate Australia about 9% of the forests are protected; for New Zealand the figure is about 43%. For South Africa, about 24% of its southernmost temperate forests are protected. For South America, about 23% of the temperate forests are afforded some protection, but the vast majority (more than 90%) of these are the wet evergreen forests of the south, mostly located in Chile. Less than 2% of the sclerophyllous and dry temperate forest are protected. An estimated 8% of Brazil's temperate mixed conifer forests are protected.

Overall, the most well protected forests, on a relative scale, are the Southern Hemisphere temperate rainforests, the Pacific wet forests of western North America and east Asia, the northernmost temperate forest (mixed with boreal elements), and mixed temperate forests in mountainous areas. The most poorly protected are dry and sclerophyll leafed forests of the Northern Hemisphere, wet and rainforest broadleaf deciduous and evergreen forests in the Northern Hemisphere (very limited in extent), and moist temperate deciduous and evergreen broad-leaved forests of the Southern Hemisphere. East Asia has the highest percentage of temperate forest types receiving no protection, followed by the Middle East and South America.

In some ways these data are misleading. Many of the forests classified as receiving protection are plantation or otherwise highly managed forests. These are largely native species forests in Europe, North America, and Asia, but they tend to be managed as homogeneous, even-aged, monocultures with consequent reduced diversity and ecosystem services. Natural, undisturbed, or old-growth forests comprise only a small fraction of the remaining forests: western Europe, 1%; eastern North America, 1%; eastern Asia, 1%; Australia, about 5% (but probably <1% is unlogged); South Africa, <1%.

Somewhat better off are New Zealand with about 25%, northwest (Pacific) North America with about 13%, and southern Chile with about 45%.

Some temperate forests are unique in that significant reforestation has occurred during the past century (about 1 or 2% increase on average per annum), primarily in Europe and eastern North America. However, most of these net gains in forest cover are intensively managed (in Europe and the southeastern United States). In northeastern North America, during the past century the landscape has reverted naturally from 50–90% agricultural to mostly forested, following the extensive abandonment of agriculture. Most of this forest is highly fragmented and fairly homogeneous, being of similar age. Consequently, the ecological functionality of these forests is limited. Elsewhere, temperate forest cover continues to decline at rates that vary from 1 to 10% pa.

Conservation and Protection Strategies

How does one develop a strategy for conserving or protecting the remaining temperate forests of the world? Some authors focus on “hot spots” of diversity or endemism. Globally, most attention has been focused on tropical systems and recently Mediterranean systems. Temperate forest-dominated systems have received less attention. For example, of Conservation International’s (CI’s) 24 hot spots, only New Zealand is a temperate zone forest-dominated locality. However, in his most recent iteration of “megadiversity countries,” Mittermeyer highlights 4 of 17 countries that contain important temperate forest biomes: China, the United States, Australia, and South Africa. Three of these (Australia, China, and South Africa) rank among the top 12 countries worldwide in species richness across phyla and species endemism. The four largely temperate countries also rank among the top globally in the number of IUCN Red Data Book (RDB) “threatened” plant species. Although these predominantly temperate floras are better known, as a group they have more RDB species than all of the tropical countries together. The WWF and the IUCN have also identified approximately 240 centers of plant diversity globally. Of these, about 15% represent temperate forest-dominated systems and another 10% represent other temperate biomes (e.g., shrublands, grasslands, and arid lands). Only 1 or 2% are boreal or polar, and the balance (~74%) are tropical.

There have been similar attempts to identify hot spots regionally. For example, WWF identified more than 100 forest hot spots across Europe, the Mediterranean Basin, and the Middle East. Regional centers of diversity can also be detected from taxon turnover. Data from the Atlas Florae Europaeae project, which compared the joint diversity of Pinaceae and Fagaceae across Europe at a 50-km grid scale, show highest joint species diversity in these two families in the Balkans, the southern Alps, the Carpathians, and the southern Pyrenees. This obviously reflects the high spatial heterogeneity in these localities.

Alternatively, conservation assessments may include such factors as taxon or clade irreplaceability, minimum area sets, minimum viable niche space, or ecosystem integrity. A study was done by the British NHM to select conservation priority

areas for selected plant groups. This exercise was done on a 10° grid globally and regionally for all of Europe on a 50-km grid. The global analysis revealed top-priority sites in eastern China, southeastern Australia, and central Chile along with six tropical areas, plus secondary centers in southern Chile, the southeastern and western United States, central and southern China, northern Japan, southwestern Europe, eastern and southwestern Australia, and southern Africa along with nine secondary centers in the tropics. Within Europe, many priority sites were identified in the Balkan Peninsula and margins of the Mediterranean (which include forested lands). However, there are prioritized areas elsewhere throughout Europe at lower densities.

World Resources Institute (WRI) provides another perspective on priority sites for forest conservation. They recognize “frontier forests”—large tracts of intact forested ecosystems sufficient to maintain viable populations of all indigenous species. This perspective includes large, wide-ranging predators and migratory species and takes into account the prevailing natural disturbance patterns. These are thus considered intact, fully functional forested ecosystems or landscapes. Very few of these are in the temperate zone, and most are under medium or high threat. This contrasts with the tropical and boreal zones, in which there are many more large tracts identified as frontier forest, even if there are substantial areas at risk. No intact forested landscapes are found in temperate Europe or Africa. In North America only one small patch of transitional boreal forest in central Ontario and discontinuous tracts of conifer forests in coastal British Columbia and Alaska (all under threat) can be considered intact landscapes. In Asia, only a few small forest patches in the inaccessible mountains of central and south-central China, boreal transition forest patches along the border between China and Russia, and the Primorski Krai region of Pacific Russia are considered intact temperate forest landscapes. All but one small patch are under threat. In South America the only frontier temperate forest is in southern Chile and adjacent Argentina. Most of this region is considered to be at risk. In Australia, only a small rainforest patch in Tasmania is classified as intact. Small patches of frontier forest occur on the west coast of the south island of New Zealand and one patch in the central north island. All are at risk except for the Tasmania rainforest.

Major Threats to Conservation

Many major threats exist for conserving the biodiversity and ecosystems services provided by temperate forests locally, regionally, and globally. Certainly a major threat is homogenization of the landscape. This is a result of intensively managing forests as near monocultures of either native or exotic species, managing landscape for similar forest age and size classes, introducing invasive exotic species, and relying globally on only a few taxa for forest plantations (e.g., *P. radiata* or *Eucalyptus*). The consequences of these landscape management strategies are reductions in local or regional diversity and alternation of many ecosystem processes (e.g., nutrient and hydrological cycles) and soil attributes. Large-scale increases in timber harvesting may well have a

negative impact on carbon source–sink relationships and atmospheric CO₂ levels.

Increasing urbanization of the landscape and continued harvesting of ever more remote forests will lead to a more fragmented landscape. The likelihood of these fragments maintaining ecosystem functionality is ever diminished. Within the next few decades, it is likely that no fully intact, functional forested landscapes will remain in the temperate zone, given current trends.

Atmospheric pollution from acid precipitation, and the associated ecosystem N and S loadings, remain prevalent in the north temperate zone and will have long-term effects. There is evidence that calcium is being rapidly depleted in acidic soils as a consequence of long-term acid precipitation. This will have cascading effects on forest soils and on major tree species performance, particularly those most sensitive to calcium levels such as sugar maple.

Projected global warming will have a major effect on northern temperate forests. The main direct effect of global warming will likely be seen in the boreal forest zone, with decreased periods of snow cover and hence changes in surface albedo. This will likely favor the expansion of temperate forests well north into the boreal zone. The community response patterns will be determined by dispersal characteristics of the biota and the availability of propagules in source populations. This in turn will be dictated by the configuration of forest fragments in the landscape.

In the Southern Hemisphere, the effects of global warming will be much smaller due to the moderating maritime influences. Atmospheric pollution effects are very negligible or very localized. The major threats to temperate forests here are deforestation, especially in South America, and the pervasive effects of introduced exotic species in plantation or as escapes. *Eucalyptus* and northern pines (especially *P. radiata*) are planted in monocultures across the Southern Hemisphere, with negative effects on biodiversity, soil attributes, and hydrology.

Conservation Objectives and Research Needs

Where do we need to focus attention to improve our understanding of temperate forests and develop a more effective conservation plan? Clearly we need better and more accurate means of mapping temperate forests and assessing their conservation status. There are large discrepancies and errors in assessing the current and potential forest cover for all forest types. We need more information on patterns of species occurrences (simply the presence/absence is sufficient) at a variety of scales throughout the temperate zone. Because distribution (and hence richness) patterns vary across spatial scales, one cannot simply rely on particular, arbitrary sample sizes (e.g., 0.04-, 0.1-, 1-, or 50-ha plots). Effort should be placed on inventorying poorly known areas, such as the Middle East. We need to have a better, predictive understanding of the links between forest structure and composition, ecosystem functions, and the effects of human disturbances.

There needs to be a concerted, manifold effort at developing a variety of different conservation strategies for temperate forests. These include targeting more protection for

forested biomes with high ratios of people to forest area and forest biomes or forest types that are poorly protected. Examples include east Asian forests in general, north temperate broad-leaved rainforests, and subtropical dry forests. Moreover, concerted effort should be placed on protecting the few remaining intact frontier forests, especially those at high risk, and old-aged forest stands particularly where these comprise miniscule components of the landscape. However, the strategy needs to be inclusive, focusing on conserving the complete spatial and temporal heterogeneity of the landscape, even if this necessitates some human husbandry of the landscape.

Strategies for identifying priority conservation sites should not simply target sites with high species diversity and/or endemism. Alternative means of evaluation need to be incorporated as well, such as phylogenetic richness and irreplaceability, range rarity, ecosystem or landscape integrity, landscape heterogeneity that incorporates migration in the face of natural and human-made disturbances, and minimum niche space for all biotic components of the landscape. Only with a manifold creative approach can we hope to come to grips with the conservation of this critical suite of temperate forest biomes.

Glossary

Culture Culture can be understood as the mental models, norms, values, codes of conduct, habits and rules which have evolved within different groups of humans to facilitate and constrain human perceptions, feelings, and actions among each other and between humans and their natural environment. Hofstede (2001, p. 10) defines culture as the “interactive aggregate of common characteristics that influence a human’s group response to its environment” and explains, with reference to Guilford (1959), that “culture is to a human collectivity what personality is to an individual.” Culture can be expressed at different levels of depth as visible and invisible manifestations. Although values are at deeper levels, tend to change slowly (Williamson, 2000, p. 597; North, 1991, p. 111) (Williamson places values at the embeddedness level of societies at which he also places norms, customs, and traditions. At that level, Williamson explains (in Williamson, 2000, p. 596), institutions change in the order of centuries or millennia. North states that institutions at that level have a “...pervasive influence upon the long-run character of economies.” Both assume change at evolutionary time scales.) and are invisible, rituals, heroes, and symbols are outer layers of cultural manifestations around this center and are visibly expressed in practices. The UNESCO Declaration on Cultural Diversity (2002) defines culture “as the set of distinctive spiritual, material, intellectual, and emotional features of society or a social group, that encompasses, in addition to art and literature, lifestyles, ways of living together, value systems, traditions, and beliefs” (UNEP, 2003).

Institutions The definition of what an institution is and what it does differs according to different models of human behavior. The cognitivist or social constructivist model and the new institutional economists’ model differ mainly in the role which the individual has in the construction of institutions. According to the social constructivist model the way humans perceive the external world (including society itself) is socially constructed and social behavior of an individual is shaped in the context and by the institutions of society. According to Scott (1995, p. 33, cited from Vatn, 2005, p. 10) institutions “consist of cognitive, normative, and regulative structures and activities that provide stability and meaning to social behavior. Institutions are transported by various carriers – cultures, structures, and routines – and they operate at multiple levels of jurisdiction.” In contrast, the new institutionalist model sees institutions as the “rules of the game in a society, or more formally, are the humanly devised constraints that shape human interaction” (North, 1990, p. 3, cited from Vatn, 2005, p. 10).

Memes Memes, in analogy to genes, are a basic unit of cultural transmission which are passed on from one

collective memory to another, also over generations, by a process of imitation (Dawkins, 2006). Examples of memes are virtues, ideas, beliefs, fashions, values, and norms.

Structural coupling Structural coupling is here referred to as the perception, recognition, and conceptualization of the natural or social environment, representation of it as cognitive or mental maps, and the adjustment and readjustment of behavior according to the valuation. This representation is not merely visual or static, it also serves as a guide for decision making and action according to a certain rationality. The cognitive guide, or compass, is part of what constitutes “culture” and valuation serves as a feedback and calibration mechanism within the process of structural coupling. Valuation informs the conscious mind about the consequences of actions guided by particular sets of values.

Valuation language Juan Martinez-Alier (2003) provides examples of languages of valuation: the economic language, the languages of territorial rights, environmental justice, livelihood, and sacredness. Valuation languages articulate particular values, concerns, beliefs, or expectations. Duygu Avci and Özkaynak (2010), for example, review valuation languages of resistance in environmental conflicts over resources in Turkey.

Value In many economic models value is something people are willing to give up something for in order to get or enjoy it (Kumar, 2010, p. 19). The Millenium Assessment (2005) has defined value as “the contribution of an action or object to user specific goals, objectives, or conditions.” Values can be viewed as manifestations of culture. They can take the form as social moral norms or as preferences and measures of importance; both strongly influencing behavior. Values guide decision making. In neoclassical economics “value” refers to the ability of a good or service to satisfy desires or wants. Values as ethical and moral norms refer to principles of what people consider to be good and bad or right and wrong. Different types of values are not always commensurable (e.g., the value of bread and the value of friendship). In neurobiology values are associated to states of the neurobiological system which produces emotions and feelings. Values are different states of affective systems of response, or emotional significance given to experiences. This understanding of values from the neuroniological perspective is relevant because values are not to be confused with objective pre-existing facts which only need to be revealed by means of specific valuation methods. Deontological positions and viewpoints emphasis norm-type of values and consequentialist positions emphasis preference-type of values. Whether norm-type or preference-type of values influence behavior depends on different rationalities of human behavior, the (social and biophysical) context of the decision making situation,

including the options the decision maker has and the individual brain, especially with regards to its level of consciousness.

Value articulating institutions According to Vatn (2005, p. 301) and Jacobs (1997) value articulating institutions are the institutional structures or the rules according to which values are articulated and according to which the valuation process is carried out. For example, contingent valuation,

multicriteria analysis and different deliberative valuation methods. These institutions define who participates, in which role, how (e.g., in meetings or individual interviews), what counts as data and what form the data should take, and the data handling process (e.g., how data are weighed or aggregated). The choice of a value articulating institution may strongly influence which preferences or values become articulated.

Introduction

There is a dual relationship between biodiversity and cultural ecosystem services. On the one hand biodiversity enables the provision of “cultural ecosystem services” which are beneficial for human use. On the other hand culture and its institutions provide a social lens through which ecosystem services are not only perceived and conceptualized but also valued. Values are culturally specific and a compass for human action, also on biodiversity. This dual and mutual relationship is interlinked and subject to change. Properties of ecosystems that people regard as useful may change, even if the ecosystem itself remains rather constant, and changes in social values may lead to changes in ecosystems and the services they provide.

In the following the authors will explore the linkages between biodiversity and cultural ecosystem services by describing what types of cultural ecosystem services are provided by biodiversity, explaining how culture shapes the way nature is perceived and valued and how these values are expressed. They examine the properties of this mutual relationship and the particular role that languages of valuation and value articulating institutions play within cultures as regulation and feedback mechanisms and for achieving sustainable outcomes from the interactions between biodiversity and culture.

Ecosystems and Their Cultural Services

Any analysis is explicitly or implicitly guided by a conceptualization of the subject matter that is to be investigated. For our purpose the concepts of biodiversity, ecosystem functions, services, benefits, and values are referred as suggested by the group of authors involved in the study on The Economics of Ecosystems and Biodiversity (Kumar, 2010, pp. 17–19). According to The Economics of Ecosystems and Biodiversity (TEEB), ecosystem functions “are defined as a subset of the interactions between ecosystem structure and process that underpin the capacity of an ecosystem to provide goods and services.” The relationship between ecological processes and structure, functions, and services, and the benefits derived and values attached to them is depicted in Figure 1. Biomass production, for example, is required to maintain a population of buffalos, which can be hunted to provide the service of food from which humans benefit. Another example related to cultural ecosystem services: the structure and processes of ecosystems and biodiversity provide information services for science, leisure or spiritual experience and cultural expression.

Ecosystem services (provisioning, regulation, habitat, and cultural) are therefore both scientific concepts and social constructs of biophysical functions that are useful for human

Figure 1 Ecosystem functions provide services for the benefit and well-being of people.

Table 1 Comparison of maximum monetary values (in \$ ha⁻¹ year⁻¹) of ecosystems services types in different biomes

	<i>Provisioning services</i>	<i>Regulating services</i>	<i>Habitat services</i>	<i>Cultural services</i>
Open oceans	22	62	0	0
Coral reefs	20,892	33,640	56,137	1,084,809
Coastal systems	7549	30,451	164	41,416
Coastal wetlands	8289	135,361	68,795	2904
Inland wetlands	9709	23,018	3471	8399
Rivers and lakes	5776	4978	0	2733
Tropical forests	9384	7135	5277	1426
Temperate forests	1736	456	2575	96
Woodlands	862	1088	0	0
Grasslands	715	2067	298	11

Note: Values are taken from min–max ranges of a number of individual case studies for each biome and show only the maximum values. The valuation studies which have been referred to for generating the values do not value and compare all services for each biome. That means, for example, the same case study in which the provisioning services of grasslands have been valued, does not also value the cultural services of the same biome, so that the values are not comparable. They stem from an attempt to provide an overview of values found in the literature for each biome but are useful for getting an idea of the importance of each ecosystem service.

Source: Reproduced from de Groot RS and Kumar P (2010) Estimates of monetary values of ecosystem services. In: Kumar P (ed.) *The Economic of Ecosystems and Biodiversity – Ecological and Economic Foundations*, pp. 368–401. London, Washington: Earthscan.

well-being (Figure 1). Provisioning ecosystem services includes, for example, the provision of food, water, raw materials, genetic resources, medicinal, and ornamental resources. Regulation services refer to services such as climate regulation, the regulation of water flows, waste treatment, erosion prevention, and the like. Habitat services maintain genetic diversity and the life cycles of species.

Examples of specific cultural ecosystem services are provided by de Groot (1992, pp. 120–128) and de Groot and Ramakrishnan (2005) and the value of cultural ecosystem services as compared to provisioning, regulating, and habitat services is shown in Table 1:

- Esthetic information and recreation, for example,
 - The value of housing in esthetically pleasing environments is often higher when houses are located in scenic natural environments.
 - For recreational purposes people look for landscapes which vary from those they are used to from daily experience. The Millenium Assessment (2005, p. 14) estimates that nature- and culture-based tourism employs approximately 60 million people and generates approximately 3% of global gross domestic product (GDP).
- Information for cognitive development, spiritual, and religious experience, for example,
 - The notion that ancestors observed the same landscape as those people grew up in and spent their childhood, can lead to a feeling of unity with nature.
 - Spiritual or religious values are often attached to nature areas, water or single species, like trees, in some societies (e.g., a holy tree).
 - Very often, in indigenous societies, spiritual and religious ties to nature are reflected in social norms and customs to ensure adequate behavior toward nature. There are examples of the values of indigenous forest gardens in West Kalimantan which had been manifested in local legal systems and sanctioning mechanisms (Gatzweiler, 2003).
 - Sacred natural sites and cultural landscapes institutionalized all over the world usually have a substantial meaning for people in the regions (UNESCO, 2003, 2008a).

- Inspiration for culture, art and design, for example,
 - Nature is used as a motive in many books, magazines, films, and other media. It is an important motive in paintings, sculptures, and popular art. Mountains, trees, leaves, or animals are used as symbols in national flags.
 - Architecture and fashion is inspired by naturally occurring shapes and designs.
- Information for education, history and science, for example,
 - Science uses functions of nature as a service of information provision in medicine or bio-technology. The estimated size of the market for bio-prospecting in 2020 is 100 million USD year⁻¹ (Bishop, 2010, p. 11).
 - The field of bionics mimics structures, processes, and systems in nature for engineering and modern technology.

The linkages between biodiversity and the diversity of cultural services it provides are manifold. The authors of the report of an international workshop on the linkages between biological and cultural diversity (UNESCO, 2008b) identified the following areas of interdependence:

- Language and linguistic diversity (e.g., terms, concepts and categories related to nature).
- Material culture (e.g., objects produced from or created by biodiversity).
- Knowledge and technology (e.g., traditional and local knowledge about places, ecological relations; early warning systems, risk management; traditional medicine).
- Modes of subsistence (e.g., resource-based livelihoods, plant and animal domestication, and breeding).
- Economic relations (e.g., management of common pool resources, partnerships based on trading natural resources).
- Social relations (e.g., attachment to places, such as sacred sites; social roles related to differential resource use; gender specific environmental knowledge; political relations defined by control over resources; legal institutions, such as customary law and contemporary conventions).

The particularity of cultural ecosystem services, however, is that they are not only perceived as such but also influence and shape the process of perception itself. The values attached by people to different cultural services is strongly dependent on the cultures of those people. In other words, observing cultural ecosystem services not only mobilizes cognitive schemata internalized by humans but also contributes to how nature-related cognitive schemata form. Most obvious is this relationship in the example of values derived from cultural ecosystem services in indigenous societies (Gatzweiler, 2004, p. 149). In this example, the values attached to individual species of local ecosystems are translated into sanctioning mechanisms and part of the local indigenous legal system. Sanctions for cutting valuable trees do not only reflect the value of the tree in terms of its use values but also the dependence of the group on an intact forest environment in which a single tree can play an essential role.

Conceptualizing biodiversity as “goods and services” provided by the ecosystem for human use is one example of a cognitive construction used in economics to guide human behavior in interaction with its natural environment. From the perspective of economics the value of the environment to people depends on the goods and services it yields. These goods and services are valued for their usefulness to human beings, and different cultures articulate their value by means of different types of ‘valuation languages’ (Martinez-Alier, 2003). The grammar of those valuation languages, i.e., the rules according to which value is articulated, is referred to as ‘value articulating institutions’ (Vatn, 2005).

Valuation languages, value articulating institutions and other systems of rules and organization including the incentives and rewards that result from such institutions and governance structures are socially constructed in human societies, and they have their own specific dynamics. A particular feature of cultural ecosystem services is that they depend on both functioning of the external environment and the internal processes of human perception, cognition, and of what valuing such “services” means.

This awareness is part of the cognitive process in which valuation plays an important feedback mechanism. Knowledge about the process of cognition and social constructions plays an important role for how people choose to value biodiversity and ecosystem services and how they are managed in accordance to those values. Knowledge regarding the importance of ecosystem functions for human well-being is fed by the information provision service of cultural ecosystem services.

Culture and Ecosystem Services

Cultural differences are fundamental in the way people conceive and act on the natural environment and also how they perceive nature and understand it as, for example, a provider of ecosystem services. Descola (in Descola and Pálsson, 1996, p. 82) suggests an analytical model to describe how different societies objectify their relationship to nature: (1) modes of identification (e.g., the relation between humans and nonhumans becomes social and through this social relation the distance between both is reduced and socially defined, like in

animism, totemism, and naturalism), (2) modes of interaction (reciprocity, predation, protection between species), and (3) modes of categorization (e.g., analogy and metaphoric similarities based on morphological resemblances). Descola’s analytical approach is useful in that it enables us to place the scientific and naturalist perspective within the Judeo-Christian tradition of control and utilitarianism, and the historical separation of social and biological sciences and the consequent epistemological distinction between culture and nature.

Other epistemological strands see biological diversity as being profoundly interrelated with human’s cultural diversity. The term ‘bio-cultural diversity’ reflects the belief that humans and nature are connected and both constitute the diversity of life on earth. As such, bio-cultural diversity includes biological, cultural, and linguistic diversity (Maffi, 2001; Maffi and Woodley, 2010) and emphasizes that the structure of ecosystems and human systems are mutually linked (Berkes *et al.*, 2000). This linkage encompasses three components (Figure 2):

1. The human brain as neural network, enabling cognition and (in combination with other brains) the social construction of what constitutes value and the production of culture.
2. Culture as collective construction within societies.
3. The natural environment, perceived as nature, biodiversity, or environmental goods and services and its information provision functions.

Culture here refers to the mental models, norms, values, codes of conduct, habits, and rules which have evolved within different groups of humans to facilitate and constrain human perceptions, feelings, and actions among each other and between humans and their natural environment.

Hofstede (2001, p. 10) defines culture as the “interactive aggregate of common characteristics that influence a human’s group response to its environment” and explains, with reference to Guilford (1959), that “culture is to a human collectivity what personality is to an individual.” Culture can be expressed at different levels of depth as visible and invisible manifestations. Although values are at deeper levels, they tend to change slowly (Williamson, 2000, p. 597; North, 1991, p. 111). (Williamson places values at the embeddedness level

Figure 2 The coevolution of culture and perception of ecosystem services.

of societies at which he also places norms, customs, and traditions. At that level, Williamson explains (Williamson, 2000, p. 596), institutions change in the order of centuries or millennia. North states that institutions at that level have a "...pervasive influence upon the long-run character of economies." Both assume change at evolutionary time scales.) and are invisible, rituals, heroes and symbols are outer layers of cultural manifestations around this center and are visibly expressed in practices.

Culture therefore has an enormous influence on how individual brains perceive their environment and how humans act on it. Through culture our natural environment is perceived, recognized, and conceptualized and thereby built into the cognitive maps that our brain helps us to construct. Such cognitive maps or internal "neuropsychological structures" (Wexler, 2008, p. 5), guide human behavior, like a compass. Especially during childhood and preadulthood the human brain is strongly being altered and shaped by culture, whereas the individual is capable of altering culture in later stages of its ontogenesis (Wexler, 2008). Culture is thereby formed through a constant adjustment process (e.g., learning) between internal (brain) and external (ecosystem) structures.

However, internal neuropsychological maps or mental maps are not "objective", one-to-one, congruent representations of the external world. Also, a map or a compass alone, do not help in deciding which direction to go and which action to take. What is useful in addition to a neuropsychological representation of the external world (cognition) is the ability to make those representations felt; that is consciousness.

Damasio (1994, 1999, 2009, 2010) explains that every representation is connected to an emotion and to feelings. Although emotions are bodily states rapidly generated in the brain stem and allow humans and animals to react without thinking, feelings are conscious perceptions (awareness) of emotional states. Feelings are between the calculative mind, which can trade off costs and benefits as cold facts without ever coming to a decision, with emotions, which weigh or value the factual analysis and enable decisions to be made. Values are different states of affective systems of response which give emotional significance to experiences.

The process of culture being formed by a constant adjustment process between internal and external structures has also been referred to as "structural coupling", a process that is structure determined and structure determining and that leads to structural congruence between two or more systems. Rizzello (1999, p. 79) has described the process as cognitivism. This process of matching internal representations with external (changing) environments (Wexler, 2008, p. 15), or structural coupling, is as important for survival as diversity in social and ecological systems. Diamond provides examples and explains the collapse of societies in history as a result of a failure to adjust established social or cultural values to the requirements of new environments (Diamond, 2011).

Applied to socio-economic and ecological systems, Norgaard (1994, p. 77) has explained structural coupling in the development process as a coevolutionary process in which he defines subsystems such as values, knowledge, technology and social organization, which interact with each other and

the environment in certain ways, depending on their specific traits or *culturgenes* (Norgaard, 2010, p. 3).

Culturgenes, according to Lumsden and Wilson (1981), or "memes" according to Richard Dawkins (2006, p. 189) are a basic unit of cultural transmission, similar to genes, which "propagate themselves in the meme pool by leaping from brain to brain via a process, which in the broad sense can be called imitation" (Dawkins, 2006, p. 192). Examples of memes are virtues, ideas, beliefs, fashions, values, and norms passed on from one generation to another through social interaction, language and imitation. In that process values are transmitted through the internalization of norms (Gintis, 2004).

According to Hofstede (2001) the way people value, think about, and behave on nature is rooted in the different layers of cultural manifestations and transferred from one person to another and one generation to another, by means of language and how value is articulated. Two ways through which the values of a culture are transmitted are through languages of valuation and value articulating institutions.

Languages of Valuation and Value Articulating Institutions

When culture is transferred from one generation to another, language and discourse play the role of important transmission mechanisms. The way people value biodiversity in different cultures is expressed in different valuation languages (Martinez-Alier, 2003, p. 79). "Languages of indigenous territorial rights, human rights, livelihood, sacredness, environmental values, esthetic values, and cultural values..." (Martinez-Alier *et al.*, 2010, p. 154) or religious languages of social justice (Martinez-Alier, 2003, p. 207) are examples of languages through which value is expressed.

Which language dominates and influences decision-making depends, amongst others, on who has the power of imposing a particular language over others (Martinez-Alier, 2001). Today one of the most dominant and influential languages of valuation is that of economics and *chrematistics* (Pack, 2010, p. 16; Marx, 1994, p. 260), which has evolved from an economic culture or *economism* (*Economism* is the "changing mix of knowledge beliefs and values related to, reinforced by, and essential to the short run operation of the industrial order" (Norgaard, 2010). Freudenberg *et al.* (2009) conceptualize *economism* around the assumption that (people) know their needs, wants, are self-interested and motivated mainly by economic incentives. In *economism* "markets are the arbiters of social exchange" and thereby *economism* "divorces material context from culture... (and)...privileges material well-being over other contributors to human health and wholeness."). It is a language used and understood by most people on earth, across all cultures. The conception of nature as a service provider stems from this economic culture. Economics as an epistemological tradition has also evolved from a specific socio-cultural context and economic values are part of culturally constructed realities and belief systems of particular societies (Wilk and Cliggett, 2007).

Economic values are expressed and communicated by means of opportunity costs and measured in monetary units

Table 2 Value articulating institutions and respective normative and epistemological stances

<i>Value articulating institutions</i>	<i>Normative and epistemological stance</i>
Contingent valuation method	<i>Cartesianism</i> : Value is pre-existing and needs to be discovered/revealed by, for example, willingness to pay questions. Separation between values and facts, human and nature. Substitutability between money values and ecosystem goods and services
Deliberative or social process methods	<i>Democracy stance</i> : Value is constructed in social processes. Previously unknown values evolve from deliberation and debate
Multicriteria methods	<i>Complexity</i> : Value is understood in terms of ranked importance. Irreducible plurality of analytical perspectives

Source: Modified from O'Connor M, Funtowicz S, Aguiler-Klink F, Spash CL, and Holland A (1998) *Valuation for Sustainable Environments. The VALSE Project, Full Final Report*. Ispra, Italy: European Commission Joint Research Centre, and Brondizio ES and Gatzweiler FW (2010) The socio-cultural context of ecosystem and biodiversity valuation. In: Kumar P (ed.) *The Economics of Ecosystems and Biodiversity: Ecological and Economic Foundations*, ch. 4, p. 163. London, Washington: Earthscan.

that Martinez-Alier (2003, p. 228) refers to as “language of chrematistics”. Despite this dominance of economics (Costanza, 1991; Common and Stagl, 2005) multiple valuation languages can be applied in decision-making, “without being previously translated into a common monetized bottom line” (Martinez-Alier *et al.*, 2010, p. 154; Zografos and Martínez-Alier, 2009). This diversification of languages of valuation is part of the diversity of values and cultures.

Along the same lines (Zografos and Martínez-Alier, 2009, p. 1726) analyzed a case study of wind farm conflict in rural Catalonia and come to the conclusion that “the absence of (diverse) opportunities for meaningful deliberation in decision making and the predominance of decisional bottom lines curtail claims to fairer distribution of costs and benefits from locally hosted energy developments, as well as alternative landscape value claims, and that this fuels conflict.”

The choice of a particular valuation language is not a “natural” process in the sense that people do not make conscious choices. Languages of valuation by cultural or interest groups (e.g., the industry, church, political parties, academics, or indigenous people) also carry political and social goals, i.e., choosing how to perceive nature, for example, as ecosystem services, is purpose driven. Ellen (in Ellen and Fukui, 1996, p. 28) explains that particular ways of conceiving the environment can serve the interest of particular groups.

“Whether reinventing an image of the noble ecological savage, or defining nature with a price tag, or constructing a shared image of the global environment, these models carry political and social goals and have far-reaching consequences” (Brondizio and Gatzweiler in Kumar, 2010, p. 153). The field of political ecology is much about the conflicts and politics of how people interact, solve conflicts and make decisions on how to shape nature (Robbins, 2004).

The political ecology aspect of valuation also explains why the linkage between cultural and biological diversity is not direct and clear, although popularly, high cultural diversity is frequently propagated as a precondition of high biological diversity. High cultural diversity can mean “many different but small culturally distinct groups” who may each have close traditional ties to their natural environment but weak decision making power. In contrast, another group of people which may be culturally less diverse but therefore dominant in their decision making influence can transform biodiversity according to the values it holds. This can lead to conservation or reduction of biodiversity by the group with more influential decision making powers and not by the group which is

culturally more diverse. Examples are plenty among the indigenous people’s movements around the world.

Although choosing a particular valuation language is driven by purpose, the way according to which values are articulated within a specific institutional and cultural setting (once the choice has been made) is determined by rules – the so-called value articulating institutions. Vatn (2005) refers to valuation methods as value articulating institutions. These institutions define certain models of human behavior and different norms of rationality and as such define the assumptions and rules under which people articulate values.

Although the institutions of “economism” can have a dominating influence on human behavior and the choice of values, the institutionalism as understood by Vatn (2005, p. 105) rejects the sole norm of rationality in welfare theory and the idea that people are merely individualistic calculators striving to maximize their own utility. Rather, as Sagoff (1988) puts it, people “act within institutions of public decision making” and these institutions, which are culturally specific, define what is right and wrong, good or bad, valuable or worthless (Vatn, 2005, p. 105; Wilk and Cliggett, 2007). Brondizio and Gatzweiler (in Kumar, 2010, p. 163) present an overview of how different normative and epistemological stances of value are related to different value articulating institutions (Table 2) and conclude that for the purpose of biodiversity valuation, choosing a value articulating institution can be more important than calculating a correct value.

Biodiversity, Culture, and Sustainability

Cultural diversity has been recognized together with biological diversity as important ingredients for sustainable development (UNEP, 2003). Although there is no common interdisciplinary conceptual and methodological framework that clearly defines the dynamic interface between biological and cultural diversity the authors have pointed to linkages which are important to consider for achieving the goal of sustainable development. On that path the “TEEB” report (Kumar, 2010) has been a milestone.

One of the core messages of the TEEB report is that while aiming at a full account of all economic values is necessary for sustainable use of biodiversity, it is not sufficient. Gowdy (1997) (in Kumar, 2010, p. 272) explains that “Biodiversity value can be seen as layers of a hierarchy moving from market value, to nonmarket value to humans, to ecosystem value.

These various levels of biodiversity value point to the need for a pluralistic and flexible methodology to determine appropriate policies for its use and preservation....ultimately economic value represents only a small portion of the total value of biodiversity and ecosystems". The backward link to culture again is that such a pluralistic methodology involves the recognition of a diversity of valuation languages and value articulating institutions, which are part of cultural diversity.

Culture as defined by the [UNESCO Declaration on Cultural Diversity](#) (the [UNESCO Declaration on Cultural Diversity \(2002\)](#) defines culture "as the set of distinctive spiritual, material, intellectual and emotional features of society or a social group, that encompasses, in addition to art and literature, lifestyles, ways of living together, value systems, traditions, and beliefs.") is (also) understood as a characteristic of people with a common mode of thinking and acting ([UNEP, 2003](#)). Although it is difficult to evaluate the impact a specific ethnic or cultural group has on biodiversity (not least because of the political ecology and political economy aspects mentioned above) it is possible to describe the quality of this relationship when considering 'a culture of acting' or an 'epistemological culture'. Different cultures of thinking and acting thereby take into account and recognize more or less different types of values. If confined to market values only, the likelihood is high that noneconomic aspects of biodiversity are left aside and the sustainability of actions remains uncertain.

A culture which attaches and communicates only a narrow set of values for biodiversity will shape biodiversity according to those values it recognizes and appreciates most. Attaching economic values to biodiversity will strengthen its resource character – those aspects of biodiversity which are known to humans, which they perceive as useful and for which they are willing to pay. The result of such behavior is the defect "economic compass": economic incentives and institutions are blind for the noneconomic values of biodiversity which are lost.

Attaching also noneconomic and intrinsic values to biodiversity ([Gatzweiler, 2008](#)), values which are difficult or impossible to express monetarily, which follow not only the consequentialist view in the tradition of economics (meaning that the value of biodiversity is a means to a higher end which is the well-being of humans.), but also the deontological position (meaning that biodiversity has a value independent from its usefulness to humans, according to moral standards independent from its usefulness or contributions to higher ends.), will shape our environment and produce cultural landscapes which can not immediately be explained by their economic usefulness to humans. Just those values however are transmitted by and produce the cultural ecosystem services.

Consequently, if the diversity of cultures per se and the diversity of values and institutions are not a sufficient explanation for the extent to which biodiversity is conserved or lost, the power and opportunity to translate values into action and implement institutions in a way that it influences behavior through effective institutional environment, could be a better explanation of the linkage between biodiversity and culture and how it needs to be shaped for sustainability. This notion on how systems of rules and governance structures

emerge in concrete action arenas and action situations in order to co-ordinate the coevolution between ecological and social systems has been operationalized in an analytical frame work developed by Hagedorn *et al.*, called "IoS" ([Hagedorn et al., 2002](#); [Hagedorn, 2008](#)) (the IoS framework provides the function of a research heuristic, which relates four key elements of institutional innovation and institutional performance in social-ecological systems (SEs) to each other: transactions, actors, institutions, and governance structures. According to the IoS-Framework, the properties of the respective transactions and the characteristics of the involved actors determine which institutions (sets of rules, norms, and values) develop and through which governance structures (organizational forms) these institutions will in practice be implemented. Ecological and social systems find themselves in a permanent process of coevolution. Each system is dependent on the other; their existence, thus, depends on their reciprocal ability to adapt. To assure such a coadaptation, "IoS" are required. These are sets of rules that, through linkages to the appropriate organizational forms, make felt their coordinating effects. They either emerge from processes of institutional change or are explicitly created. IoS, thus, take over a coordinating function between social and ecological systems and order their reciprocal influences. The relationship between humans and nature is, thus, seen as a socially constructed culture, in which the emergence or creation of new institutions or institutional change is always a question of reasons or drivers, which may or may not be of a practical nature. They result from, for example, the desire to economize on transaction costs or resolve conflict between actors, but may also have reasons that are far beyond such economic or interest-based motives, for example, preserving nature for its own right. This approach has two main advantages: Firstly by including nature-related transactions the impact of Ecological, biological, geological, and other physical systems on how cultures evolve and how they shape our habits and behavior is explicitly made a part of analyzing SEs. Secondly, it enables such analyses of those institutions and governance structures which represent nature-related and socially obstructed cultures such as biodiversity cultures to become concrete and operational. This contributes to a better and also more detailed understanding of processes of institutional and organizational change with an emphasis on the rules, norms, values and organization of the use, and protection of natural systems such as soil, water, air, energy, climate, biodiversity, genetic resources, vegetation and animal populations, ecosystem, and natural common-property goods such as fish, forest, game, and rangeland resources.)

To conclude:

- a. The cultural ecosystem services comprise a set of largely nonconsumptive benefits valued for their contribution to human well-being.
- b. These services are frequently among the most valuable nonmarketed ecosystem services.
- c. A particular feature of cultural ecosystem services is that they not only depend on the functioning of the external environment but also on the internal processes of human perception, cognition and of what valuing such services means.

- d. Consciousness is being aware of the self and which role it plays in the cognitive process in which valuation plays an important feedback mechanism.
- e. The values of cultural ecosystem services frequently lie outside the market, are incommensurable, and are expressed in valuation languages that are culturally specific. Different valuation languages play an important role in conflicts over access to resources and recognition of rights.
- f. For the purpose of biodiversity valuation and depending on the socio-cultural context of valuation, the choice of a particular value articulating institution can be more important than calculating a correct value.

Achieving society's equity, sustainability and efficiency goals requires that they all be taken into account in social decision-making. This pluralism of valuation systems can be taken into account by maintaining diversity of valuation languages and not restricting the choice of diverse value articulating institutions.

Biofuels and Biodiversity: The Implications of Energy Sprawl

Bruce A Robertson, Smithsonian Conservation Biology Institute, Washington, DC, USA, and Michigan State University, East Lansing, MI, USA

Glossary

Agricultural intensification The use of advanced tools and techniques, including pesticide and fertilizer applications and the removal of hedgerows that separate fields, that allow for an increasing amount of food or biomass to be produced from a given amount of land.

Agroenergy The production of biofuels as plant crops in agriculture, as distinct from biofuels produced synthetically or from algal culture.

Biofuel Any fuel that is in some way derived from biomass, including firewood, methane, and petroleum. Globally, the production of plant-derived liquid fuels for use in transportation is the primary focus of biofuel production.

Cellulosic ethanol production Ethanol production that employs the conversion of cellulose, the primary structural molecule of most plants, into glucose that can then be fermented into ethanol.

Cropping system An integrated system of agricultural production, including the crop selection, management, harvest, distribution, processing and marketing.

Energy sprawl An increase in the agricultural land area required for the production of dedicated biofuel crops that replaces food crops, natural and seminatural habitats, and other land uses, occurring directly from land-use change or indirectly due to biofuel-related market conditions.

Feedstock The plants or plant-derived products (e.g., pellets) that can be used to produce biofuels. *First-generation* feedstocks are those that are currently under wide cultivation for the production of ethanol and biodiesel, including corn, soy, sugarcane and palm oil. *Second-generation* feedstocks (e.g., switchgrass) are those crops that are currently not widely cultivated for biofuels but have high potential yields.

"Biofuels and Biodiversity: The Implications of Energy Sprawl" refers to the potential trade-off between the increase in development of agricultural crops for biofuels and the ability of agricultural landscapes to support biological diversity. Evaluations of the impacts of biofuels on biodiversity have received much attention in recent years due to an increasing demand for the development of alternative energy sources focusing on the fundamental question of whether the development of biofuels is at odds with the conservation of biodiversity.

The Promise of Biofuels

Although humans have relied on biofuels like firewood for nearly half a million years, today the term is primarily used to refer to plant-derived liquid fuels, like ethanol, that are most commonly used for transportation. Biofuels, including their development and production, have become a central component of the national energy strategies of many countries, especially in North America and Europe, because they have shown promise for augmenting energy security, supplementing existing energy supplies, and providing a new source of income for rural economies, all with a reduced environmental impact when compared with fossil fuels (see [Figure 1](#)). And even though the balance of greenhouse gas emissions associated with biofuel production has become a major environmental concern, liquid biofuels have already become a significant source of transportation fuel supplies in many countries due to production subsidies, import tariffs, and other legislation enacted by producing countries. The US, for example, enacted the Energy Independence and Security Act of 2007 that mandated that the volume of renewable fuel

blended into transportation fuel should increase from 9 billion gallons in 2008 to 36 billion gallons by 2022. Interest and investment in biofuels is occurring on a global scale.

It is the production of liquid biofuels from plants grown as dedicated agricultural crops (agroenergy) that has the greatest potential to impact biodiversity on a global scale. More than 30 plant species have been proposed or are currently grown as bioenergy crops. Those more commonly mentioned are listed in [Table 1](#). The most economically important bioenergy crops in the temperate zone are corn, soybeans, and canola – annually sown plant monocultures. In tropical regions, biofuel production is dominated by sugarcane and African oil palm, a perennial tree whose biodiversity consequences are given more extensive treatment in one of the chapters of this encyclopedia. Yet, so-called cellulosic biofuel technology is projected to expand the range of plant species (i.e., second-generation feedstocks) that can be used to produce biofuels. By facilitating the use of perennial native plants that can be grown in polycultures and that require less crop management activities and chemical inputs, second-generation biofuels may provide more stable, seminatural environments with significant potential to maintain biodiversity in agricultural landscapes.

Determining whether or not growth in bioenergy can or will benefit biodiversity, help mitigate ongoing biodiversity losses, or only contribute to ongoing population declines in populations of native species depends on a number of factors. These include the relative suitability of biomass feedstocks as habitat, the relative habitat value of crops and other land uses that biomass crops replace, the impacts of practices used to grow and harvest crops, and the importance of landscape context in shaping local habitat quality. Therefore, we summarize the predicted biodiversity responses to three aspects of

Figure 1 Conceptual model for the implementation of conservation strategies to abate the negative impacts of energy sprawl on biodiversity. A complex set of drivers will ultimately determine which crops are selected for production in various agricultural regions, how they will be managed, and what land-use impacts will follow (left side). Conservation strategies designed to mitigate the impacts of agroenergy production to biodiversity targets can focus on crop selection and management or agroenergy-driven land-use change (right-center). Broad cooperation will be required to development productions standards designed to meet conservation goals for biodiversity (far right). Guidelines for the production of agroenergy crops and biodiversity monitoring must be tied to strategic land-use planning within the context of producer incentive programs while incorporating provisions for the conservation of critical habitats. The impact of conservation strategies on feedstock selection and management and its direct and indirect impacts on agroenergy-related land-use change will need to be monitored for its effectiveness in meeting conservation goals. Failure to meet goals can lead to revisions of conservation strategies within an adaptive management framework.

Table 1 Candidate plant species for dedicated agricultural biofuel production

Annuals	Perennials
Corn	Willow
Sunflower	Hybrid poplar
Canola (rapeseed)	Castor bean
Barley	Sweetgum
Sunflower	Reed canary grass
Sugarbeet	Miscanthus
Camelina	Switchgrass
Peanut	Jatropha
Lesquerella	Babassou palm
Mustard	African oil palm
Alfalfa	Sugarcane ^a
Cuphea	

^aRequires multiple plantings.

bioenergy expansion: (1) which crops are selected for production, (2) how crops are managed, and (3) how land-use changes at landscape and regional scales affect local biodiversity. Each factor may have both positive at negative impacts on biofuel production and biodiversity conservation.

Biodiversity Responses to Crop Selection and Management

Within the context of field-grown biofuel crops, biodiversity may comprise the plants used as feedstocks themselves, plant

species able to successfully coexist with crops (e.g., weeds), soil microorganisms that cycle nutrients and decompose organic matter, and the various forms of vertebrate and invertebrate animal life that can utilize biofuel crops as habitat. Research into biodiversity responses to existing and new types of biofuel crops has lagged behind their production. There is a distinct lack of information demonstrating the relative biodiversity value of alternative bioenergy crops and how various management activities mitigate or exaggerate any differences that might influence decisions about crop selection that incorporate biodiversity concerns. As such, our summary of biodiversity responses reflects an inherently incomplete understanding of biodiversity responses to bioenergy production informed by general principals of biodiversity responses to agriculture in general.

Biodiversity responses to the intensification of agricultural practices are generally negative (Matson *et al.*, 1997; Donald *et al.*, 2001; Tscharntke *et al.*, 2005). As crops are sewn more densely, leaving fewer hedgerows and adjacent natural or seminatural habitats, and farmers increase the frequency of disturbance to cultivated lands by applying fertilizers and herbicides and increasing the frequency of harvest, fewer species are able to persist in agricultural fields. Because plant species' diversity is also linked to animal species' richness both within agricultural settings and among more natural habitats (Haddad *et al.*, 2001, 2009), vegetation diversity within a field and at local and landscape scales should influence biodiversity responses. Both the relative habitat stability (annual vs. perennial) and floristic diversity of a bioenergy crop should then

Figure 2 The relationship between crop plant special richness, perennality, and biodiversity. Monocultures of plant species that must be replanted annually and that require higher chemical inputs generally support lower local biodiversity. Crop rotations reduce the need for inputs. Longer-lived woody species are not harvested annually. Biodiversity should be highest in bioenergy crops consisting of diverse, largely perennial plants that experience less disturbance associate with tilling or the application of chemical inputs.

influence biodiversity responses. Selection of crops across these axes is expected to have predictable consequences for biodiversity as dedicated bioenergy crops enter agricultural landscapes (Figure 2).

First-Generation Biofuel Crops

Many of the most economically important biofuel crops in the world (e.g., corn, soybeans, and canola) are annual monocultures that must be reseeded by farmers each year (Table 1). Corn is the dominant bioenergy crop throughout much of North America, and its production has grown dramatically in response to US legislation financially encouraging its production and the blending of ethanol with gasoline. Ethanol is produced from corn through fermentation of the starchy portion of the corn kernel. It is commonly rotated with soybeans, a feedstock also used for the production of biodiesel.

Feedstock Selection

Corn is commonly rotated with soybeans, and this rotation system supports a relatively species-poor biological community (Gardiner *et al.*, 2010; Fletcher *et al.*, 2011). Only a few common species of breeding birds commonly nest in cornfields. Mammal and arthropod diversity and abundance are similarly reduced in corn and soybean when compared to other seminatural habitats (e.g., set-aside lands) and alternative crops. As a rule, species that are most likely to be found breeding in corn and soybean fields are generalists with relatively wide geographic ranges and stable populations and subsequently of low conservation priority.

Canola, or rapeseed, is a flowering member of the Brassicaceae family grown in monoculture primarily for its seed, which has been historically used to produce cooking oil and as animal feed. Its high oil content (38–39%) in comparison

to soybeans (18–19%) has made it an increasingly important feedstock for the production of biodiesel. This crop is increasingly common in China, Canada, and Europe, which produces more than 3/4 of the world's supply. Despite its wide geographic extent and economic importance, canola's ability to support biodiversity relative to other crops and habitats has not been well quantified.

Feedstock Management

Crop management can profoundly affect biodiversity responses independently of the type of biofuel crop selected for production. It is the intensity with which these annual crops are managed that negatively impacts their inherent ability to support biodiversity. Perhaps the two most important types of local management that will influence the magnitude and direction of effects of biofuel crops on biodiversity are the application of chemicals and the harvest regime (timing, type, and frequency of harvesting) (Fletcher *et al.*, 2011).

Expansion of corn, soybean, and canola production resulting from energy sprawl is almost certain to result in increased use of pesticides and fertilizers, which is, for example, the single largest input for US corn production (Hill *et al.*, 2006). Fertilizer runoff causes nutrient eutrophication in streams and rivers that reduces habitat availability and diversity for native organisms and directly kills them by creating anoxic conditions. Most notable among these is the great "dead zone" in the Gulf of Mexico, in which nutrient-enriched runoff from the Mississippi river results in oxygen depletion of seawater, killing most sessile and slow-moving organisms in a near-shore area of 13,000–21,000 km² (the size of the US state of New Jersey). Fish have some ability to swim away from anoxic areas, but anoxia and other consequences of eutrophication from runoff have resulted in reproductive problems in fish that involve decreased size of reproductive organs, low egg counts, and lack of spawning. Consequently, fertilizer use associated with the production of annual biofuel crops represents an important biodiversity threat to aquatic and marine ecosystems.

An estimated 70–90% of ground-applied pesticides and only 25–50% of aerially applied pesticides actually reach their target area (WWF, 1999). Pesticides have direct effects on target and nontarget organisms, including native bees and hoverflies, which are important pollinators of both crops and native plants (Kearns and Inouye, 1997). Endocrine disruptors impact bird, reptile, fish, and amphibian populations through their ability to cause physical abnormalities (WWF, 1999; Guillette *et al.*, 1999), reduce fertility, compromise immune systems, and trigger metabolic and behavioral abnormalities. Magnification of these effects through food chains can lead to community-level drops in biomass and diversity that may be irreversible in the near term (WWF, 1999) and that extend far beyond the borders of feedstock plantations.

Genetically modified herbicide-tolerant (GMHT) varieties of corn, soybean, and canola of these crops are in widespread use and have further reduced the biodiversity value of these feedstocks. GMHT varieties impact the richness and abundance of plant species in and around arable fields due to the efficacy of the herbicides applied in controlling weeds and reducing their seed banks (Firbank *et al.*, 2008). Loss of plant diversity leads to reduced insect diversity and longer-term reductions of weed populations, which in turn affect animal

populations higher up the arable food chain by altering the quality and quantity of forage resources (e.g., Watkinson *et al.*, 2000). In this way, maximizing crop production through elimination of fast-growing plant competitors creates a bottom-up trophic cascade that reduces the diversity and abundance of organisms at higher trophic levels.

Machinery used in chemical applications and in the harvest of crops can directly impact plants and animals in crop fields. Bird nests are commonly trampled or destroyed by passing machinery and adults may be killed as well when they are caught unaware or are incubating eggs or protecting young. Mortality and reproductive failure is also a problem for a host of mammal and arthropod species and lead to local population declines. These losses can easily lead to population declines. By eliminating the use of pesticides and reducing disturbance the use of conservation tillage, cover crops and organic farming regimes for corn and other crops can increase the diversity and reproductive success of birds and otherwise enhance biodiversity (Warburton and Klimstra, 1984; Lokenmoen and Beiser, 1997; Beecher *et al.*, 2002; Henderson *et al.*, 2004; Hole *et al.*, 2005) and may be useful approaches in the production of bioenergy crops where biodiversity conservation is a priority.

Collectively, first-generation biofuel crops consisting of annual monocultures associated with high levels of chemical inputs and disturbance are poor reservoirs for biodiversity in agricultural landscapes. Expansion of the acreage of these crops at the expense of other crops and natural and seminatural habitats certainly have negative impacts on biodiversity with strong potential to impact a broad taxonomic range of organisms extending far beyond the borders of biofuel plantations and to affecting terrestrial, marine, and aquatic biological communities.

Second-Generation Biofuel Crops

Conventional biofuels are produced only from the starchy or oily portions of the fruit and seeds of first-generation feedstock species, representing only a fraction of the overall biomass of the plant. In addition, these are the same portions of plants required by the food industry. Cellulosic technology is a new method by which lignocellulose, a primary structural molecule in most terrestrial plants and a large portion of the plants overall biomass, is converted to sugar that can be converted to liquid fuels via pyrolysis, gasification, or fermentation. As one of the most plentiful organic molecules on Earth, lignocellulose represents an enormous untapped source of energy that could be produced from a vast range of feedstock species including nonfood plant materials such as cereal straws and corn stover (leaves and stems) as well as dedicated energy crops. Although a large array of second-generation feedstocks have been proposed and are being developed for production (Table 1), short-rotation woody crops and perennial grasses are currently considered to be the most efficient and sustainable feedstock for bioenergy production in temperate regions (Adler *et al.*, 2007; Karp and Shield, 2008; Russi, 2008; Williams *et al.*, 2009; Bringezu *et al.*, 2009).

Second-generation biofuels show promise for benefitting biodiversity on a global scale where they replace first-

generation crops or other annual cash crops. Fuel can be processed from native plant species that have adapted to cope with and thrive in the face of regionally important pests, diseases, and weather conditions. As a corollary, native plants and animals that have coevolved with native feedstock species can provide benefits (e.g., nitrogen fixing, pest resistance) that increase plant yields while providing habitat for native plants, animals, fungal partners, and other microorganisms. This same reasoning opens the possibility that native plants can be economically produced in polyculture that should further enhance within-field biodiversity at other trophic levels by adding floristic and structural diversity. By supporting native species, such crops have the potential to enhance ecosystem services such as natural pest control, and subsequent economic benefits can extend outward into agricultural landscapes to benefit other nonbiofuel crops. In addition, most candidate feedstocks are perennial species that neither require replanting on an annual basis nor require substantial fertilizer and herbicide inputs. In this way, second-generation crops house great potential to experience substantially reduced machinery-related disturbance and represent increased habitat stability that benefits the persistence of diverse taxa in agricultural landscapes of which biofuels are a part. These more diverse, low-input, perennial feedstocks are more likely to benefit biodiversity (Figure 2).

Cellulosic technology is currently available, but further research is required to increase its economic efficiency so that second-generation crop production systems can effectively compete with other cash crops. It is generally thought that the process will become commercially viable and begin to industrialize and expand on a global scale in the years 2017–2023.

Agricultural wastes that are currently in heavy supply will very likely be the first major feedstock for the production of cellulosic ethanol. Foremost among these are the corn leaves and stalks remaining after harvest (e.g., corn stover). Stover has already come into demand as a cellulosic biomass feedstock. However, because stover removal negatively impacts soil nutrient content, expansion in its use as a fuel is predicted to increase demands on conventional farmland (Wilhelm *et al.*, 2007). Unfortunately, the financial incentives for stover removal are projected to be much greater than those to leave residues on the land to protect soil and water resources or retain as stubble and ground cover for the benefit of grassland birds and other wildlife (Cruse and Herndl, 2009). And even though the intensification of land already in high yield production will likely impact biodiversity, these costs must be weighed against the biodiversity cost of putting additional lands (i.e., energy sprawl) into production, even if low-intensity or organic farming methods are used. These same concerns will affect the extraction of wastes from other agricultural operations (e.g., forestry).

Short-rotation Woody Biomass

Short-rotation woody cropping systems include silvicultural operations designed to produce woody biomass over relatively short harvest cycles (1–15 years) using intensive silvicultural techniques and high-yielding tree varieties. Species like cottonwood and poplar (*populus* spp.) as well as willow (*salix* spp.) have come into production in North America and Europe, primarily for the pulp and paper industries. Yet this

same pulp can be converted to liquid fuel via cellulosic technology and so these crops have garnered attention as next-generation agroenergy crops.

Like first-generation biofuel crops, short-rotation woody crops are typically grown using intensive techniques, including fertilizers, pesticides, irrigation, and the control of competitive species. Because several species regenerate by producing multiple new shoots from stumps left after harvest, they are often coppice harvested. This is a key ecological benefit of these plant feedstocks in that it eliminates the need for more extensive disturbance of soils associated with annually resewing crops.

Short-rotation woody biomass systems may be considered intermediate to managed forest plantations and contemporary agrosystems in terms of their associated management inputs and implications for biodiversity (Burger, 2002). Indeed, diversity of birds and mammals and plants are typically lower on short-rotation woody plantations compared with slower-growing managed and unmanaged forests. Fauna associated with stands of fast-growing trees are extremely dynamic and transition from species assemblages that are more similar to those of open fields to those that are more akin to shrubland. In general, these woody plantations tend to favor shrub-associated vertebrates at the expense of cavity nesting and other species associated with mature forests (Riffell *et al.*, 2011). These crops tend to also accumulate and maintain more diverse communities of butterflies, spiders, and other invertebrates than annually harvested row crops (Dauber *et al.*, 2010). However, populations of some herbivorous arthropods (e.g., leaf-eating beetles, Coleoptera: Chrysomelidae) can increase to levels that cause significant crop damage, suggesting pesticide use could become necessary, which could negatively impact the diversity of nonpest invertebrates. Replacement of other managed or native forests by short-rotation crops will have significant negative biodiversity consequences (Archaux and Martin, 2009). Collectively, research on the relative biodiversity value of these crops in comparison to the agricultural, seminatural, and natural land-cover types they replace is extremely limited. Furthermore, information regarding the biodiversity associated with plantations of most of the remaining candidate woody species – for example, loblolly pine (*Pinus taeda*), alder (*Alnus* sp.), and black locust (*Robinia pseudoacacia*) – is largely absent.

Perennial Monocultures: *Miscanthus* and Switchgrass

Commonly referred to simply as *Miscanthus*, *Miscanthus giganteus* is a hybrid of two perennial grass species native to parts of Asia (*M. sinensis* and *M. sacchariflorus*). This large rhizomatous grass is endemic at latitudes up to 45°N and produces dense stands of very high biomass even under temperate climatic conditions (Lewandowski *et al.*, 2000; Hastings *et al.*, 2009). It appears to have the largest energy yield and energy use efficiency of all potential bioenergy crops (Sims *et al.*, 2006; Heaton *et al.*, 2004) in part due to reduced fertilizer requirements. For this reason, many consider *Miscanthus* to be the top candidate for production as an agricultural crop dedicated to cellulosic ethanol production. Some estimates suggest that even though a typical acre of corn yields around 7.6 t of biomass per acre and 756 gallons of ethanol, *Miscanthus* is capable of producing up to 20 t of biomass and 3250 gallons of ethanol.

In Europe, *Miscanthus* can support a relatively higher diversity of birds, arthropods, and weedy plants (Semere and Slater, 2007b; Bellamy *et al.*, 2009), including sensitive species when compared to other managed perennial crops and grasslands. Yet its spring harvest creates a tall overwinter stand structure that is relatively unsuitable for many vertebrates. This harvest schedule and *Miscanthus*'s relatively low chemical input requirements may reduce disturbance and mortality, which affects plant, bird, and mammal breeding in *Miscanthus* stands. This very limited information is also tempered by the fact that *Miscanthus* is an exotic and potentially invasive species in North America even as it is being considered for large-scale production. Its ability to support native biodiversity in this novel setting and its potential impacts on biodiversity should it become invasive are unknown.

Switchgrass (*Panicum virgatum*), another perennial grown in monocultures, is a warm-season grass native to the North American tallgrass prairie whose expansion in cultivation has been assumed will enhance biodiversity in agricultural landscapes. It has been selected as a model energy crop by the US Department of Energy also due to its high water and nitrogen use efficiency and its regionally adapted genotypes (McLaughlin and Walsh, 1998). It can form dense stands in monoculture and is often grown by farmers enrolled in government-sponsored agricultural set-aside programs to benefit biodiversity.

In some regions of the Midwestern US, switchgrass is currently under limited cultivation as a biomass feedstock for coal-fired power plants (e.g., Roth *et al.*, 2005), but it is not yet in large-scale production for purposes of cellulosic biofuel production. Switchgrass monocultures or near-monocultures support a larger and more enhanced diversity of breeding, wintering, and migratory birds, arthropods, and mammals than traditional corn and soybean row crops (Robertson *et al.*, 2011a, b; Fletcher *et al.*, 2011). This includes an enhanced diversity and biomass of functional groups of arthropods important in pollination, pest control, and nutrient cycling (Gardiner *et al.*, 2010; Landis and Werling, 2010). Compared to contemporary biomass crops, switchgrass also appears to enhance the diversity of the bird species of the highest conservation priority (Fletcher *et al.*, 2011).

Native Polycultures

Evidence indicates that diverse grasslands such as restored or reconstructed prairies containing as little as 60% grass can act as sustainable sources of cellulosic biomass (Tilman *et al.*, 2006; Garlock *et al.*, in preparation). Although high-diversity grasslands require more land area to produce a given amount of energy (Fargione *et al.*, 2009), they also require only a single planting, minimal cultivation, and low chemical inputs, which may improve their economic feasibility as a fuel sources.

The relative field-scale biodiversity value of such agrosystems has been explored largely in North America by comparing biodiversity responses to prairie remnants and grassland reconstructions to switchgrass monocultures and corn-soybean rotations. Diversity and abundance of breeding and migratory birds and terrestrial arthropods all are greatest in native prairie remnants, similar but lower in diverse prairie reconstructions, and generally elevated relative to switchgrass monocultures and cornfields (Gardiner *et al.*, 2010; Bakker

and Higgins, 2009; Landis and Werling, 2010; Robertson *et al.*, 2011a, b). This advantage also extends to arthropod groups effective in pollution and pest control.

New Approaches to Biodiversity Management

Collectively, candidate cellulosic biomass feedstocks all show positive effects on species richness for all taxa yet studied (Dauber *et al.*, 2010). These differences are due to pest- and weed control measures, vegetation structure, harvesting patterns and bottom-up impacts of plant diversity and productivity on higher trophic levels. Because many second-generation cellulosic crops are not yet under commercial cultivation, management regimes associated with field studies are commonly unrepresentative of those that will impact biodiversity in industrially managed fields. Consequently, the apparent biodiversity advantages of perennial monocultures and polycultures are likely overestimates.

The selection of genets and management techniques that maximize agricultural yields, for example, are known to reduce biodiversity in agricultural settings in general (Green *et al.*, 2005) and bioenergy crops specifically (Robertson *et al.*, 2011a). For example, perennial native plants like switchgrass may require little or no fertilizer but economic interests in maximizing crop yields suggest that fertilizers may still be a part of even these types of production systems (Fike *et al.*, 2006; Scott and Tiarks, 2008; Varvel *et al.*, 2008). Pesticide applications will obviously reduce the diversity and abundance of arthropod and weed populations, but may also affect vertebrate populations and are known to correlate with biodiversity loss on a global scale (Mozumdera and Berrens, 2007). Expanded research into the application of natural or integrated pest control in next-generation bioenergy crops may play an important role in mitigating biodiversity losses associated with crop management. For example, the introduction of a stable perennial ground flora may be useful in controlling competitive weeds in woody-biomass plantations and native monocultures and polycultures tend to sponsor greater arthropod-mediated pest-control services than row crops (Werling *et al.*, 2011).

Harvesting times and patterns are known to be of importance to some birds (Roth *et al.*, 2005), and novel harvest strategies, including partially harvesting fields and staggering harvests among fields, may be important strategies for managing biodiversity at the field scale. These techniques could enhance structural diversity and complexity, which are known to enhance species richness and abundance of birds in perennial grasslands and short-rotation plantations (Robertson *et al.*, 2011a, b). Such approaches will also benefit biodiversity in biomass plantations by enhancing species turnover and providing a continuous reservoir from which arthropods, mammals, and other less-mobile taxa can repopulate new biomass plantings (Christian *et al.*, 1997; Hanowski *et al.*, 1997).

Landscape-Scale Biodiversity Considerations

Understanding the dynamic responses of biodiversity to changing agricultural landscapes is fundamental to understanding

how best to guide conservation efforts. Like other modern agricultural crops, the production of biofuels will have impacts on biodiversity by altering the structure and composition of the landscapes in which they are produced (Firbank, 2008; Landis *et al.*, 2008), with impacts on biological communities depending on their ecological traits (Burel *et al.*, 2004). Spatial heterogeneity is associated with biological diversity in biofuel crops (Dauber *et al.*, 2010) and agricultural landscapes in general (Benton *et al.*, 2003). Increasing this diversity may be a fundamentally important contribution of biofuel production to biodiversity conservation as biofuels enter existing agricultural landscapes that are commonly dominated by a few intensively managed crop types (Cook and Beyea, 2000). As a corollary, biomass plantations are likely to have adverse effects on biodiversity where they enter landscapes of high conservation value (Anderson and Fergusson, 2006; Schulz *et al.*, 2009) or where the biodiversity they harbor is only a subset of that already found in the surrounding landscape (Britt *et al.*, 2007; Baum *et al.*, 2009; Schulz *et al.*, 2009).

Spatial Considerations and Landscapes

The spatial extent and configuration of biomass crops within a landscape will profoundly shape their suitability for particular taxa. Avian diversity and abundance, for example, commonly increase as patches of habitat become larger and more habitat is available for area-sensitive or edge-avoiding species (Ribic *et al.*, 2009b; Johnson and Temple, 1990; Winter and Faaborg, 1999). North American bird species associated with switchgrass and mixed grass and forb plantings such as prairie reconstructions are commonly those that evolved to exploit various types of grassland habitats (Murray *et al.*, 2003; Roth *et al.*, 2005). Larger patches of these feedstocks will not only hold more species but also increase bird diversity per unit area as well as increase the likelihood of rare and sensitive species colonizing these fields (Herkert *et al.*, 1996; Robertson *et al.*, 2011a, b). Habitat patches within landscapes with a greater proportion of suitable habitat are also more likely to attract rare and sensitive species (Bakker *et al.*, 2002). In this way, production on large spatially concentrated fields of grass-based biomass crops could enhance populations of highly imperiled group of birds where they replace other crops (Robertson *et al.*, 2011a). Interspersion of grass-based and woody-biomass crops could have negative effects on grassland birds if grown in a predominantly agricultural and grassland landscape (Bakker and Higgins, 2009; Fletcher and Koford, 2002; Coppedge *et al.*, 2001; Renfrew and Ribic, 2008). Inasmuch as the economics of ethanol production are predicted to cause aggregation of crops in the vicinity of processing plants (Graham *et al.*, 2000), there is the potential for altering agricultural landscape structure, with positive consequences for grassland bird communities. Similar benefits may accrue on other continents or in woody-biomass systems, but research is lacking.

Plant diversity appears to be maximized at a very small patch size in modern short-rotation woody plantations (Kroiher *et al.*, 2008). Because plant, mammal, and bird species richness commonly decreases from edges toward more central and insular portions of habitat patches, the

edge-to-area ratio of a patch can affect the diversity and abundance of species in a patch (Christian *et al.*, 1998; Weih *et al.*, 2003; Ribic *et al.*, 2009b), and this pattern may accumulate over time, for example, as woody biomass stands develop more complex habitat structure (Cunningham *et al.*, 2004).

In contrast to birds, arthropod diversity and abundance are less often linked to patch size but commonly increase as the diversity of habitats and land-use types in the landscape surrounding a patch increases (Simberloff, 1976; Summerville and Crist, 2003). This suggests that there exists a trade-off such that crop placement favoring one biodiversity component may negatively impact other important taxa. When crop placement and landscape-scale management needs of multiple taxa come into conflict, conservationists and land managers will require strategies that prioritize biodiversity components whose populations need the most help in particular regions or landscapes.

Finally, noncrop areas such as headlands, waterway buffer zones and harvest accesses to woody crops are important features for biodiversity that enhance populations of noncrop plants, birds, butterflies, native bees, and other arthropods (Anderson *et al.*, 2004; Marshall *et al.*, 2006; Haughton *et al.*, 2009; Bellamy *et al.*, 2009). Ultimately, the strategic placement of biomass plantings within existing agricultural landscapes has the potential to buffer disturbance regimes and edge effects in remnant patches (Brockhoff *et al.*, 2008) and increase the connectivity of natural habitats for animal populations (Hanowski *et al.*, 1997; Firbank, 2008), therefore enhancing local and landscape-scale biodiversity. However, because landscape-scale biodiversity responses are, in part, emergent properties of field-scale responses of organisms to crop selection and management, the benefits of landscape-scale management will be contingent on biodiversity-friendly agricultural practices by individual farmers.

Agroenergy Sprawl and Biodiversity

Land-use change is considered one of the major drivers of biodiversity loss on a global scale. Perhaps the greatest threat that bioenergy production represents to biodiversity is its role in driving farmers and governments to convert biodiversity rich natural and seminatural habitats to biomass production. Economically important contemporary agroenergy crops like corn, soybeans, sugarcane and African oil palm have all been singled out for their negative biodiversity impacts associated with land-use change (Groom *et al.*, 2008; Robertson *et al.*, 2008; Eggers *et al.*, 2009; Fargione *et al.*, 2009; Fletcher *et al.*, 2011). European and North American countries and Brazil have legally mandated sustainable energy standards that require an increasing component of liquid biofuel in their national energy budget. Their respective governments have created financial mechanisms that have encouraged rapid and large-scale expansion in biofuel production. In the US, it is estimated that at least 206,000 km² of new cultivated land will be needed to meet US energy demand by 2030, an area roughly equal to the size of the state of Kansas (West *et al.*, 2009; McDonald *et al.*, 2009). The suitability of particular biomass feedstocks will vary according to

geographic region (Evans *et al.*, 2010), and some biodiversity rich regions will be largely inappropriate for the production of bioenergy from ecological and economic points of view. The land area needed for biofuels is expected to disproportionately reduce the extent of some habitats more than others (e.g., temperate grasslands; McDonald *et al.*, 2009), thereby increasing the vulnerability of species that currently rely on these land-cover types. Biodiversity associated with temperate grasslands has already been drastically reduced through habitat conservation to agricultural use, so further changes associated with bioenergy production have potential to be particularly damaging.

A fundamental question regarding the land-use impacts of bioenergy on a global scale is whether bioenergy crops will replace existing crops or lead to the loss of natural and seminatural habitats with a resulting net loss in biodiversity. To a large degree, this question remains unanswered. American sustainable energy policies have largely been drawn based on the assumption that most energy-crop production will occur on sites already in use for agricultural production, and so far most of the expansion in corn production has come from land previously used for other crops, especially soybeans (Secchi and Babcock, 2007; USDA, 2009). Yet increasing production mandates are rapidly increasing demands on agricultural lands and favoring conversion of native prairie or seminatural grasslands associated with set-aside programs to corn-ethanol production (Secchi and Babcock, 2007; Stephens *et al.*, 2008; Fargione *et al.*, 2009). By one estimate, current trends in the US are projected to lead to losses of 121 million ha (30 million acres) in the prairie pothole region alone (Rashford *et al.*, 2011).

Government policies that provide economic incentives for farmers to produce bioenergy crops lead to more indirect forms of land-use change. For example, in the US farmers have reduced their rotation of corn with soybean plantings in response to federal ethanol subsidies (Secchi and Babcock, 2007). Reduced soybean supply has led to higher global soybean prices and increased clearing of Amazonian rainforest to grow this crop. The European Union's goal to produce 10% of its transport fuel from renewable sources by 2020 is projected to drive farmers to convert 69,000 km² of wild lands into fields and plantations, an area twice the size of Belgium (Bowyer, 2010). However, a recent analysis has indicated that indirect land-use changes induced by increased production of biofuels in the US are negligible or nonexistent (Kim and Dale, 2011). Such conflicting results highlight the newness of energy sprawl issues as well as the need for further investigations of land-use changes.

Potentially mitigating the direct and indirect losses of native and seminative habitat supporting important biodiversity components is the possibility of growing perennially based feedstocks on degraded lands or those with relatively nutrient-poor soils, so-called marginal lands (Fuentes and Taliaferro, 2002). Targeting biomass production on abandoned farmland or other lands unsuitable for the production of more traditional crops are considered a way to satisfy the acreage demands required for next-generation fuels (e.g., Hoogwijk *et al.*, 2005; Field *et al.*, 2008). It remains unclear if sufficient marginal lands exist to satisfy a significant fraction of current biofuel production goals in producing countries. More

important, marginally productive lands in Europe and the US are frequently enrolled in government-sponsored set-aside programs that provide payments to farmers for not producing crops on easily erodible or otherwise unused lands.

Regardless, if the biofuel production benchmarks of producing countries are to be met, it will mean large-scale, highly significant land-use changes will take place over relatively short timescales (EEA, 2006; Tuck *et al.*, 2006; McDonald *et al.*, 2009; West *et al.*, 2009; Fischer *et al.*, 2010). Projected biofuel-driven land-use change in Europe in the near future is predicted to negatively impact a broad range of taxa, including reptiles, butterflies, and birds (Louette *et al.*, 2010). These biodiversity impacts are unlikely to be uniformly distributed across agricultural landscapes. Transportation costs dictate a need for economic supply basins surrounding production plants that could easily lead to large-scale monocultures and the segregation of landscapes for energy production from those for food production and biodiversity conservation (Dauber *et al.*, 2010). In this way, economic forces may preclude the ability of strategic landscape design to manage biodiversity in biofuel production landscapes (Bellamy *et al.*, 2009). Consequently, and in the absence of government intervention, whether or not bioenergy production can be effectively integrated into multifunctional landscapes that are socioeconomically and ecologically sustainable will depend on economic markets and the distribution of crop production and processing infrastructure (Berndes *et al.*, 2008; Porter *et al.*, 2009; Dauber *et al.*, 2010).

In summary, our framework of identifying the biodiversity consequences associated with crop selection and management and land-use change is an attempt to parse the individual contributions of these variables to biodiversity loss. Clearly, though, crop traits (e.g., perennality) do much to dictate important biodiversity-related management regimes associated with crops (e.g., mechanical disturbance type and frequency). Moreover, crops traits like perennality influence the economics of crop-selection decisions for producers because these crops often take at least a year to establish themselves before they can be harvested. Producer decisions about crop selection influence land-use change at large spatial scales that, in turn, shape the biodiversity consequences of local crop management. These connections among impact categories and spatial scales are common in agricultural systems and are intertwined with the evolving socioeconomic and technological advancements that shape the economics of crop selection and the efficiency of management techniques. If biodiversity conservation is to succeed in the face of biofuel-driven global change, we will need to explicitly address and exploit these connections and systematic inputs in designing sustainable production systems.

Strategies for Biodiversity-Friendly Energy-Crop Production

Strategies to implement biodiversity-friendly energy-crop production arise from a variety of contributing factors (Figure 1). The design and implementation of landscapes that provide for both biofuels production and biodiversity conservation may yet be achieved with careful consideration and

design as highlighted by an approach that follows a mitigation hierarchy (Fargione *et al.*, 2010). As a first step, areas that primarily provide biodiversity and valued ecosystem services must be avoided (Keeney and Nanninga, 2008). Increases in biofuel production have many consequences, including the removal of lands from conservation set aside programs that provide biodiversity benefits, a movement toward producing crops in marginal areas (e.g., degraded or abandoned cropland), an increase in the diversity of feedstocks that can be used in producing biofuels, potential development of lands that were previously never considered as production landscapes. Therefore, as a first step in avoiding negative biodiversity and ecosystem service impacts, areas that provide such services must be identified and protected.

A second step of the mitigation hierarchy focuses on minimizing detrimental impacts through the use of best management practices not only within the fields that produce biofuel feedstocks but also across broader biofuel production landscapes. Such management can be accomplished through crop selection, novel management strategies, and strategic land-management approaches. Although economic concerns will drive much of crop selection, some crops will better diversify the land-cover composition of agricultural landscapes, thereby accruing more substantial biodiversity benefits. Asynchronous harvesting regimes among field and partial harvesting of focal fields have potential to create mosaics of agroecological habitat differing in their structure that will directly benefit taxa like birds that select breeding and migratory habitat based largely on structural considerations (Roth *et al.*, 2005; Robertson *et al.*, 2011a, b) but also benefit a diverse range of taxa (Sage and Robertson, 1996; Baum *et al.*, 2009; Fargione *et al.*, 2009; Gardiner *et al.*, 2010) and the ecosystem services they provide (Isaacs *et al.*, 2009; Landis and Werling, 2010). Such strategies may also have the secondary effect of broadening within- or between-field habitat structural diversity the following spring and summer by increasing standing dead vegetation where fall regrowth has occurred (Benton *et al.*, 2003; Murray and Best, 2003; Roth *et al.*, 2005).

A strategic landscape-scale approach to biofuel crop placement could also enhance biodiversity in ways that have not traditionally been considered in agricultural systems (Paine *et al.*, 1996). Set-aside programs in North America and Europe already provide for the planting of perennial grassland or other plants along streams or as buffer strips that are known to benefit birds, pollinators, and other species. Biomass crops may also act as ecotones, buffers around natural areas, or act to enhance connectivity between structurally similar natural habitat types (Cook and Beyea, 2000; Dauber *et al.*, 2010). These options can further enhance more straightforward biodiversity benefits of diversifying the land-cover in agricultural landscapes.

Additional consideration must also be given to factors that drive the development and production of biofuels (Figure 1). Primarily, there must be consideration of both increases in fuel efficiency as well as increased development and production of alternative-energy vehicles (Wiens *et al.*, 2011). Such conservation measures can have a significant impact on the demand for biofuels as a major contributing factor to the potential impacts of energy sprawl (McDonald *et al.*, 2009). Additional consideration must also be paid to the full suite of

impacts across the entire life cycle of biofuel production. Life-cycle analysis (LCA), an approach designed to evaluate economic, environmental, and social impacts from the development to the delivery of a product, can be used to evaluate the potential costs and benefits of different feedstocks (Jenkins and Alles, 2011; Wiens *et al.*, 2011). Ideally, such analyses are tailored to the specific feedstock as well as the specific landscape in which it is produced.

The Role of Policy Development Inconserving Biodiversity

Ultimately, the prospects for capitalizing on the biodiversity benefits of such options are remote in the absence of government intervention. Although the preceding recommended strategies primarily focus on land management, the drivers of energy sprawl will require policy-level solutions. In the US, where production targets, subsidies, and blending targets have been used to encourage corn production and are now being used to encourage the production of cellulosic crops, environmental standards for the production of biomass crops have not yet been created. In contrast, the European Union (EU) has begun to address bioenergy production issues through the revised Fuel Quality Directive (European Commission Environment, 2009) and the Renewable Energy Sources Directive (EU-RES-D, 2009). These standards prohibit the production of biomass from land with high biodiversity value (including native grasslands), promote the use of contaminated or marginal lands through a bonus system, mandate that biomass be produced in accordance with EU standards (e.g., cross compliance, good agricultural and environmental conditions), and require that practices outside of the EU be monitored and specified through agreements with producing countries. Although indirect land-use impacts are not fully considered (Hennenberg *et al.*, 2009) and production of biomass remains allowed on lands enrolled in set-aside programs (which otherwise cannot be used for production under EU agricultural rules), European standards remain the most stringent and well developed in the world. Still, 0.9 million ha (2.2 million acres) of the set-aside area have been used in recent years for nonfood production. In addition, by focusing on species richness and abundance as measures of programmatic success, agri-environmental schemes have largely overlooked the habitat requirements and management needs of specialist species (Filippi-Codaccioni *et al.*, 2010). Moreover, the EU has neither yet set minimum sustainability standards for all bioenergy against negative environmental and social impacts nor established a robust and verifiable system of certification for biofuels. As leading global producers of biofuels, the US lags far beyond in nearly all of these critical steps necessary to maintain biodiversity as bioenergy production expands.

As biofuels become a global commodity, there will become an increasing urgency for global-scale cooperation in the development, implementation, and enforcement of biofuel production standards. Given the already serious implications of indirect land-use change that cross international borders and the eventual likelihood of international markets for biofuel production, there will be a critical need for international

cooperation for the creation of methods that encourage crop selection, management, and production systems that mitigate biodiversity losses associated with land-use change, maximize biodiversity in agricultural landscapes through landscape-scale strategic planning and incentive program, develop rigorous biodiversity standards for producers, and create a role for the enforcement of those standards. Such standards will be insufficient unless they are broadly implemented through production regions (Hennenberg *et al.*, 2009) via grower incentives and effective land-use planning that will need to be implemented by the governments of producer nations. Economic incentives associated with land set-aside programs appear to be a particularly opportune means of encouraging that productions standards are met.

Because responses to biomass crops and their landscape context will vary across biodiversity components (Dauber *et al.*, 2010), specific production guidelines will be needed for rare and sensitive species within a larger policy that more broadly targets the conservation of biodiversity and ecosystem services (e.g., pollination, pest control). In this regard, a strategic land-use planning approach that incorporates the value of private (unprotected) lands (e.g., Wilson *et al.*, 2010) may be useful. Such strategies are capable of revealing not only where to invest but also which strategies to invest in to effectively and efficiently conserve biodiversity. Finally, the effectiveness of programs in accomplishing conservation goals will need to be monitored. Mechanisms such as ecological cross compliance, in which farmers have to meet environmental standards to qualify for acreage-related direct payments, may be a potentially powerful instrument in this regard (Aviron *et al.*, 2009).

Summary and Open Questions

Will energy sprawl necessarily have a negative impact on biodiversity? Are bioenergy production and biodiversity conservation compatible or mutually exclusive? The answer to these questions clearly depends on the type of crop in question, the previous use of the land on which it is being cultivated, whether its management includes provisions to mitigate biodiversity losses or actually enhance its value as wildlife habitat, and on the details of national and international policies that mandate its ecological sustainability.

Further hindering a clear picture of how bioenergy production will impact biodiversity is a broad array of knowledge gaps. First, we still know too little about the biodiversity associated with various biofuel crops, especially important candidate next-generation crops (e.g., *Miscanthus*). Some species are being proposed as crops outside of their native range and where their potential to become invasive and to displace native biodiversity is unknown. Second, our understanding of how next-generation crops are to be managed is largely speculative as these crops are only recently entering agricultural production. Because crop management can profoundly impact field-scale biodiversity, it will be critical to understand how the evolving economics of bioenergy production systems will allow for flexibility in management that mitigates biodiversity impacts. Our ability to develop realistic and sustainable producer guidelines and best practices will be

contingent on an improved understanding of the economics and logistics of crop management. Further confusing the relationship of crop selection and management and biodiversity are the unknown effects of genetic modifications of feedstocks that lead to altered crops structure and pesticide and herbicide resistance.

There exists a complex interplay between socioeconomic and environmental factors in determining the impacts of bioenergy production on biodiversity. In addition to the role of national bioenergy policies and market forces in affecting direct and indirect land-use change, for example, biofuel production has the potential to accelerate global warming or even reduce available freshwater supplies (Evans and Cohen, 2009). Developing scientifically based criteria for the sustainable production of bioenergy will be difficult unless we develop a framework for assessing the risk to biodiversity associated with socioeconomic and environmental conditions that constantly incorporates new knowledge. Bioenergy production should be considered a major threat to the persistence of biodiversity and ecosystem services on a global scale. Yet next-generation crops have substantial promise to benefit biodiversity should they be strategically integrated into existing agricultural landscapes. Polycultural feedstocks such as mixed grass and forb prairie, for example, could have profoundly important benefits for rare and declining species associated with temperate grasslands while providing fuel and a range of other ecological benefits such as pest control (Werling *et al.*, 2011). Ultimately, economically viable and sustainable bioenergy production, integrated with food production, may yet be feasible. Realizing the biodiversity potential associated with cellulosic bioenergy will be dependent on some profound changes in agricultural policies in producer countries, a renewed focus on interdisciplinary research, the ultimate economics of industrialized bioenergy production systems, and international cooperation to ensure that environmental and biodiversity costs of biofuel production are not simply exported elsewhere.

Glossary

Anthropocene Current era in which human impacts on land cover, biogeochemical cycling, water quality and availability, and other major features of Earth now rival nonanthropogenic forces.

Conservation refugee Person who, as a result of the establishment of a protected area, has been displaced without fair compensation from the areas in which she or he lived, hunted, foraged, or grazed livestock.

Ecosystem services Goods and services ranging from medicines and building materials to oxygen, clean water, and flood control that natural ecosystems deliver to people.

Integrated conservation and development

project Project that seeks to simultaneously protect nature and improve human well-being.

Kuznets curve Hypothesized trend in which pollution and other environmental degradation initially rise, then level off, and eventually decrease as incomes increase and the national economy develops.

Payments for ecosystem services Financial rewards for individuals who protect habitats so that the provision of natural goods and services can continue; payments may be made by private parties that benefit from the delivery of those ecosystem goods and services or by a governmental or other agency.

Conservation is a response to the extinctions, habitat loss, and ecosystem degradation caused by human population growth and environmentally damaging or resource-extractive human activities. Thus, people are the reason why conservation, as both a scientific and a sociopolitical enterprise, is necessary. At the same time, conservation is fundamentally an expression of human values, with motivations for conservation ranging from religious or ethical to material and economic. Thus, conservation exists because of the effects of people on the nonhuman biosphere, and the scope, goals, and implementation of conservation are shaped by people. However, conservation is arguably conducted not only because of people but also for people. Conservation seeks to protect biodiversity as well as ecosystems that provide highly valuable and potentially irreplaceable products and services for both current and future generations of humans. Although conservation exists, at least in part, for the benefit of humanity, many of the actions performed in the name of conservation have harmed people and their interests. Displacements of human communities and restrictions on human activities are enacted presumably for the greater good of both nature and humanity. However, the distribution of benefits and harms among different human communities has been highly uneven, causing some observers to question the ethical basis for certain conservation practices. This article explores four dimensions of the complex relationship between people and conservation: (1) people as a conservation threat; (2) people as the creative force, shaping conservation's goals and actions; (3) people as victims of conservation; and (4) people as beneficiaries of conservation.

People as a Conservation Threat

The cumulative effect of people on the natural world is conservation's *raison d'être*, and one dimension of conservation research entails the measurement of human threats and the

development of strategies to reduce the negative effects of people on nature.

Measuring and Mapping Human Threats to Conservation

The effects of people on the planet, sometimes cumulatively called the "human footprint," increased greatly over the last century, largely because of explosive human population growth combined with vastly increased per capita consumption of natural resources. The human population is now approaching 7 billion and is continuing to grow at a rapid pace. The United Nations predicts a population of 9–10 billion people at the end of the current century. The growth of the human population in developed nations has slowed, and in some wealthy nations the population is shrinking. However, the population in developing nations continues to grow rapidly.

Feeding the anticipated 9 billion plus people will require enormous increases in agricultural production. Production of crops, including those used for fiber and biofuels, is and will continue to be a major pressure for conversion of habitats to agricultural uses. Unless agricultural practices are radically improved, crop production will cause even greater land conversion, water withdrawals, environmental pollution, and loss of topsoil. In addition to agricultural products, the additional billions of people will increase demand for fish and seafood, freshwater, wood products, fossil fuels, and just about every other natural resource imaginable. As a result, many nonhuman species will face even greater loss of their habitats and increased mortality stemming from direct harvest, pollution, and altered ecological interactions due to, among other factors, species introductions.

The spatial coincidence of tropical areas of high biological diversity and future human population growth (Cincotta *et al.*, 2000) is a matter of great concern for conservationists. However, scientific assessments of the planet find negative effects of

human activities everywhere. Birds, fish, and whales in remote arctic oceans have flesh contaminated with chemical pesticides. The nitrogen cycle and hydrological cycle are now dominated by humans – human activities produce 60% of all the fixed nitrogen deposited on land each year (Kaiser, 2001), and people appropriate more than half of the annual accessible runoff (Postel *et al.*, 1996), leaving little freshwater for other species. Human modifications of habitats include deforestation, draining of wetlands, impoundment of rivers, urbanization, pollution, species introductions, climate change, and overharvest of plants, fish, and other wildlife. Scientists have coined a name for this era – the Anthropocene – to emphasize that we have entered a new geological era in which human influences on land cover, biogeochemical cycling, water quality and availability, and other major features of the world now rival or even surpass nonanthropogenic forces (Steffen *et al.*, 2007).

Various researchers have produced maps to illustrate the distribution and intensity of the human footprint. An especially well-known assessment led by scientists at the Wildlife Conservation Society defined the human footprint on the basis of population density, land transformation, accessibility, and electrical power infrastructure (Sanderson *et al.*, 2002). These efforts consistently reveal that few places remain relatively unaffected by humans. One outcome of the growing human footprint is species extinction. Although the rate of extinction has been overestimated by many scientists (He and Hubbell, 2011), it is clear that large numbers of species are at risk.

Analyses of the oceans, which might seem from a distance to be unspoiled, reveal a similar picture of widespread human impacts. In fact, a team of scientists concluded that more than 40% of the world's oceans are strongly altered by human actions, and no ocean area is unaffected by people (Halpern *et al.*, 2008). Ocean impacts – including dredged ocean bottoms, overexploited fish stocks, and pollution – are not as immediately visible as are terrestrial changes such as deforestation, but their effects on biodiversity and the delivery of ecosystem services are just as dramatic. Humans influence virtually everywhere on the planet, no matter how remote. Adding atmospheric pollutants and global climate change to the tally, it is safe to say that human activities have altered all of the planet's lands and waters in profound ways.

It is easy to attribute the negative effects of people on the natural world to ignorance and greed. However, many of the negative outcomes are simply trade-offs from activities meant to improve the human condition. People purposefully try to kill off predators such as wolves to reduce predation on their livestock, people build dams to improve navigation and irrigate crops during dry periods, and people drain wetlands to reduce mosquito-transmitted disease. These activities are attempts to tame or domesticate nature for the safety and health of people. Although the domestication of nature has pushed many nonhuman species to the brink of extinction and sometimes beyond, humans have enjoyed profound benefits including improved nutrition, health, and longevity (Kareiva *et al.*, 2007).

Given the negative effects of people on the natural environment, it is of the utmost importance, not only for conservation but also for human welfare, that society move quickly

to reduce the rate of human population growth. However, the raw number of people on the planet is not the only factor determining the human impact on nature. *Per capita* consumption of natural resources also plays an important role. Heightened *per capita* demand for everything from indoor plumbing and refrigeration to meat, automobiles, and portable electronic devices, translates into more use of natural resources and therefore more pressure on ecosystems and nonhuman species. There is hope that economic development may predispose societies to take better care of the natural environment. For example, the amount of certain pollutants initially increased but later decreased as a function of economic growth. This so-called Kuznets relationship has been documented in some cases, but there is so far no evidence that it holds for conservation-related activities or outcomes (Dietz and Adger, 2003). The other big hope for reducing human impacts on the planet lies in technological developments. If crops can be produced using less water and less fertilizer, if alternative energy sources can be adopted on a large enough scale, if use of recycled materials can reduce the reliance on wood, cotton, and other natural resources, then there is yet hope for reducing the human footprint, despite the foreseeable growth and increasing prosperity of the human population.

Conservation Strategies to Reduce Human Threats

Beyond measuring and mapping human impacts, conservationists design strategies to reduce the negative effects of humans on ecosystem function and biological diversity. A major conservation strategy has been the establishment of protected areas. The International Union for Conservation of Nature (IUCN) describes a protected area as a “clearly defined geographical space, recognized, dedicated and managed, through legal or other effective means, to achieve the long-term conservation of nature with associated ecosystem services and cultural values” (Dudley, 2008). Conservationists typically seek to identify and protect places that harbor long lists of species, or species of particular concern, or habitats that are relatively undisturbed by human activities. The degree to which human activities are curtailed within protected areas varies from strict exclusion of people to community-managed areas that incorporate traditional levels and modes of resource use.

Conservationists initially set a goal of protecting 10% of the world's land area. That goal has since been surpassed, and approximately 13% of the world's land area is now under some level of conservation protection (Jenkins and Joppa, 2009). Establishment of marine protected areas (MPAs) has lagged behind that of terrestrial protected areas. Conservationists now seek to protect 10% of the planet's marine area, or at least 10% of marine areas within 200 nautical miles of land. These goals for global protection were set in the absence of reliable data on the number and extent of MPAs. Thanks to a concerted data-collection effort, researchers documented the existence by 2006 of nearly 4500 MPAs covering only 0.65% of the world's oceans (Wood *et al.*, 2008). This rather paltry coverage means that conservationists have a long way to go to meet even the most modest goal of 10% coverage of areas within 200 nautical miles of land.

In addition to setting aside particular areas for protection, conservationists often seek legal limits on human activities that might harm species at risk of extinction or particularly important habitats, such as wetlands. The US Endangered Species Act, Canada's Species at Risk Act, and Australia's Environment Protection and Biodiversity Conservation Act are but a few examples of national laws that restrict human activities in the name of conservation. The degree to which activities are limited varies from country to country, but many nations have adopted the approach pioneered in the USA of compiling a list of at-risk species that on listing gain additional protections.

In the USA, the presence of a listed animal species on privately owned land can greatly curtail the activities of landowners. On federally owned lands, the presence of a listed animal or plant can precipitate such restrictions. In addition to prohibiting direct harm to individuals of the listed species, the law may prohibit economic activities such as farming, grazing, harvesting trees, and the construction of roads and buildings, if these activities will reduce the amount or quality of habitat for the species. Even very large, economically important activities, such as the construction of a dam, may be halted. Such was the case when construction of the Tellico Dam on the Little Tennessee River was stopped because the proposed dam would submerge and destroy the habitat of a small endangered fish known as the snail darter (*Percina tanasi*). Litigation of this case went to the US Supreme Court (*Tennessee Valley Authority v. Hill* 1978), and the Court ruled that indeed the dam could not be completed because to do so would extirpate the snail darter. Many people were astonished by this decision because \$110 million had already been spent on the project (Mann and Plummer, 1995). The Court's decision made the snail darter a symbol in the highly polarized pro-development versus conservation controversy. The prodevelopment sector ridiculed the snail darter as a tiny (less than 8.5 cm in length), useless fish that should never trump the jobs and economic benefits associated with a dam. The conservationists argued that the dam was not needed and would not benefit people as claimed.

Conservationists have implemented a broad range of strategies to protect biodiversity and ecosystem services. The two examples discussed here – protected areas and legal restrictions on human activities that could harm at-risk species – illustrate that the primary focus of conservation is eliminating or at least mitigating the negative effects of human activities. Because such restrictions can have economic consequences, conservation actions can be controversial.

People Define Conservation Goals and Priorities

Broadly speaking, conservationists seek to protect nature. But what exactly is "nature," and what places, species, or other entities are considered worthy of conservation attention and investment? Debate about these issues makes clear that the concept of nature is a human construction, shaped and designed for human ends. For example, portrayals of nature as either a fearsome, dark power or as fragile and feminine vary across cultures and are subject to change over time. Similarly, the targets of conservation attention and the goals by which

conservationists measure their success are human constructions, reflecting societal values and whims. Three issues – shifting conservation baselines, the wilderness ideal, and the disproportionate attention given to large-bodied vertebrate species – illustrate some of the ways in which conservation priorities reflect human values.

Shifting Baselines

The phenomenon of shifting baselines illustrates just how malleable conservation goals can be (Pauly, 1995). Shifting baselines refers to how people's perception of the "normal" state for an ecosystem changes across generations. For example, as one generation of fishers replaces the previous one, any sense of how abundant or large the fish once were is lost (Sáenz-Arroyo *et al.*, 2005). Or consider that until recently there was little recognition that Yellowstone National Park once harbored large populations of jackrabbits (*Lepus townsendii*; Berger, 2008). The past presence of these rabbits in Yellowstone, along with their recent decline, is much more than a historical curiosity; it could help explain the sometimes intense conflict between today's wolf population and domestic livestock. Wolves might not have such a large impact on livestock if an ample number of jackrabbits were still available as prey.

Shifting baselines are potentially problematic because, once the memory of past conditions is lost, it becomes all too easy to accept today's depleted conditions as normal. And since everyone, including conservation managers, is susceptible to this phenomenon, the state of the natural world is ratcheted ever downward. Moreover, with so little knowledge of what has been lost, there is less urgency and motivation for sound management of today's resources.

Attitudes toward introduced species are also susceptible to the phenomenon of shifting baselines phenomenon. Conservationists generally seek to prevent species introductions, and they often try to control or eliminate certain harmful introduced species because these invaders can cause extinction of native species and disruption of ecosystem services. However, the desire to control or eliminate invasive species is not universal. The picture can become murky when the invader provides valuable ecosystem services. For example, plantations of nonnative trees can sometimes be more productive, retain nutrients better, and even have greater total diversity (albeit nonnative diversity) than native forests.

The Nile perch (*Lates niloticus*) provides an example where groups of people have very different attitudes about a highly invasive species. Most scientists view the introduction of the Nile perch to Lake Victoria as an ecological nightmare. This fish, intentionally introduced in 1954 to provide food and income for local communities, caused the extinction of possibly hundreds of fish species native to the lake. However, the Nile perch did indeed provide boom fishery harvests and was at least temporarily of great benefit to the local people, particularly because it increased employment. The perch itself is now overfished, and its economic benefits have declined. Concordant with fishing-induced declines in the perch, many native species, including some that were thought to have been lost from the lake, are enjoying a resurgence (Baliro *et al.*, 2003). The ultimate fates of the Nile perch and of native fish

diversity in Lake Victoria are still uncertain, but local support for eradication or control programs aimed at Nile perch is minimal and unlikely to gain traction. To the contrary, the perch fishery is viewed as needing better management. The most likely scenario for Lake Victoria is that a new “ragamuffin” (Marris, 2009) ecological community will develop, with some extinctions of native species (but not as many as originally thought), and with the Nile perch and other species representing a commercially important fishery. In other words, the perch will become integrated into the lake’s ecosystem, and what is “natural” will be redefined to include it.

One does not have to look hard to find invasive species that many people are fond of and would hate to see removed. Human values play an important role in determining which species introductions are considered calamitous and which are considered indispensable. In fact, intentional introductions may become an important tool in conservation, potentially used to move species threatened by climate change to areas with more favorable conditions and to replace the ecosystem functions previously performed by now extinct species (Marris, 2011). Clearly, conservation goals are a reflection of both scientific and societal understandings of what conditions are normal or desirable in nature.

The Wilderness Ideal

In western conservation, “pristine” wilderness, relatively untouched by humans, is given high priority for protection. The US Wilderness Act defines wilderness as “an area where the earth and community of life are untrammeled by man, where man himself is a visitor who does not remain.” This definition reflects the view that humans and wild nature are incompatible. Whether or not one agrees with this point largely depends on whether one views people as a part of nature or an unnatural force, external to nature (Adams and Hutton, 2007; Ereshefsky, 2007). Surveys in the USA indicate that people overwhelmingly see themselves as part of nature, yet the majority paradoxically describe a natural environment as one that is free from human presence or influences (Vining *et al.*, 2008).

The human-nature dichotomy has profoundly influenced conservation thinking and practice. The creation of at least some protected areas via the displacement and exclusion of human communities – what some people term “fortress conservation” (Wilshusen *et al.*, 2002) – is one important manifestation of this worldview. However, given the extensive human effects on the planet and that protecting wilderness may first require moving people out of the area, some question whether wilderness truly exists or is merely a mental construct. Even the supposedly “virgin” rainforests have in fact been subjected to a long history of slash and burn agriculture and were dotted with surprisingly large human settlements (Willis *et al.*, 2004).

Preferential Treatment for Large-Bodied Vertebrate Species

The role of human values in shaping conservation priorities also manifests itself in the set of species that have become the icons of conservation. Entire organizations are devoted to the conservation of certain animal species such as cheetahs,

elephants, and gorillas. Other species may not have their own organization looking out for their interests, but they receive a disproportionate amount of conservation funding. Species such as the giant pandas, rhinos, whales, and lions that adorn the magazines and calendars of conservation organizations are not representative of biological diversity. In fact, the majority of species are various kinds of insects. In contrast, the species that have been elevated to the status of conservation icons tend to be large-bodied vertebrate animals.

The concept of biodiversity is in some ways an attempt to level the playing field and give more or less equal value to all types of species. According to this view, if the goal is simply to protect the longest lists of species, a nematode or beetle species would count as equivalent to a bird or mammal species. But this impartial treatment of species is not reflected in actual conservation practice. Invertebrate animals comprise 84% of all animal and plant species in the USA and more than one-third of all at-risk US species (Goble *et al.*, 2006), but they account for only 14% of the species listed under the US Endangered Species Act. Funding for conservation of at-risk species also disproportionately favors vertebrates, especially iconic species. For example, in the 2004 fiscal year, 20 listed vertebrate species received more than 50% of US federal and state conservation expenditures that could be attributed to particular species (USFWS, 2006). Moreover, although plants make up about half of the federally listed species, they receive less than 10% of the funds for recovery (Schemske *et al.*, 1994).

Conservation goals reflect human ideas of what nature “should” look like. These goals change over time as a function of generational amnesia about past conditions and changing societal preferences for different types of landscapes and species.

People as Victims of Conservation

Conservation can sometimes seem like a movement that is antipeople, entranced by sentimental longings for pristine wilderness untrammeled by humans and unmarred by cities. Conservation’s misanthropic reputation has arisen, in part, because millions of people have been forced off their land so that animals and habitats could be preserved (Dowie, 2009). Hunters and farmers in some Asian and African nations contend that protected areas limit their diet and earnings. In the USA, farmers, fishermen, and loggers are angry about losing their water privileges or their jobs because of fishing restrictions and other endangered species protections. These problems are discussed in the following sections in the context of conservation refugees and the negative economic effects of conservation.

Protected Areas and Conservation Refugees

In the process of creating protected areas, conservation has harmed people by displacing communities, stripping them of their access to wildlife and other natural resources, and potentially aggravating poverty and hunger by limiting opportunities for agricultural and other economic development

(Adams and Hutton, 2007; Dowie, 2009). The frequency with which the establishment of protected areas has displaced people and the exact number of people affected have not been well quantified (Brockington *et al.*, 2006), but at a minimum the history of such events traces back to the forced relocation of Native Americans during the 1872 establishment of Yellowstone, the world's first national park.

One example illustrating the conflict between protected areas and people concerns the Maasai. The Maasai are pastoralists who traditionally migrate with their cattle herds across the savannahs of eastern Africa. In 1947, the Amboseli ecosystem in southern Kenya and eastern Tanzania was declared a National Reserve and grazing was restricted. The Maasai who had grazed their cattle in Amboseli for many generations were angered. The 1971 declaration of Amboseli National Park was accompanied by additional restrictions including a ban on hunting. The Maasai were promised compensation for their losses, but they received little and began pressuring the government to return the lands (Dowie, 2009). In 2005, Kenyan president Mwai Kibaki returned Amboseli National Park to its original Maasai inhabitants. This controversial decision reflects a growing global discontent with such preemptory displacements.

Forced eviction of local people is not just a social injustice; it can also accentuate human threats to conservation if the local people fight back. When the Amboseli Maasai did not receive compensation they had been promised, they fought back by killing wildlife and leaving the carcasses of rhinos and leopards near popular camping spots (Dowie, 2009). In another example, the 1982 creation of Uganda's Mburu National Park was followed in 1983 by the violent and uncompensated eviction of approximately 4500 families from the area. In 1986, under a new government, the dislocated people were encouraged to resettle their former homelands. On their return, they slaughtered the park's wildlife and vandalized its facilities with the goal of pressuring the government to degazette the entire park. The government did return approximately 60% of the original park area to the people. Even after that concession, conservationists realized that the entire park would fail without the support of surrounding communities. Thus conservationists made concerted and relatively successful efforts to improve relations with the local people via regular meetings, education programs, and sponsorship of community initiatives such as the construction of schools and clinics (Turyaho and Infield, 1996).

Critics have pointed out that it is poor, often indigenous, and always politically weak groups that are uprooted from their homes. In contrast, the people who reap the benefits of protected areas and get to enjoy their scenic beauty and wildlife often are tourists, wealthier and typically whiter than the displaced people. Although modern conservationists do not overtly endorse a racist agenda, early conservation heroes John Muir, Teddy Roosevelt, and others openly expressed their disdain for indigenous groups. This is not just a historical matter – conflicts between conservation and the rights of indigenous and other local communities are ongoing. Some, and perhaps many, of conservation's successes in terms of land protection entail a dark side of racism and oppression.

Conservationists are increasingly acknowledging these injustices and are working to improve the social equity of their

strategies and actions. For example, a group of major international conservation organizations recently formed a Conservation Initiative on Human Rights. This consortium is working to develop and implement a set of principles concerning human rights in the context of conservation.

Negative Economic Effects and Unemployment

Conservation strategies, including the establishment of protected areas and legal protections for at-risk species, seek to prohibit or limit certain human activities. Resource-extractive activities such as logging, fishing, mining, and withdrawal of freshwater are popular targets for conservation restrictions. Other activities that alter habitats, such as agriculture, grazing, and construction of roads and buildings, also may be limited. These limitations can come at the expense of food production, economic gain, and jobs.

Conservation laws in some nations, such as Canada's Species at Risk Act allow regulators to weigh the economic consequences of conservation restrictions. Others, such as the US Endangered Species Act call for decisions based solely on the best science available with no consideration of economic factors. As described earlier, the use of the US Endangered Species Act to halt construction of the Tellico Dam is one example of how conservation regulations may upend development plans, regardless of the economic effects.

Other examples of conflicts between conservation and jobs abound. In the 1990s, the US federal government halted timber harvesting on publicly owned land in Oregon and Washington because logging jeopardized the continued existence of the northern spotted owl (*Strix occidentalis caurina*). As a result, sawmills were shut down, and rural towns across the Pacific Northwest suffered severe economic hardship. Out-of-work loggers expressed their displeasure by displaying bumper stickers proclaiming, "Save a logger, eat an owl!" Another flashpoint for conservation involves restrictions on the amount of water allocated to farmers. In these cases, there tend to be powerful economic lobbies on both sides of the debate – farming on one side and salmon fisheries on the other. But, at least in the USA, the decisions about how to allocate water between farmers and endangered fish species are supposed to remain blind to the economic consequences.

Some conservationists believe that economic growth is in direct conflict with conservation because increased resource consumption directly translates into increased pressure on wildlife (Czech, 2000). However, others see economic development as a necessary prerequisite to achieving conservation goals. Regardless of one's views on economic development, it is undeniable that the negative economic consequences of conservation actions, loss of jobs, and limitations on the rights of private landowners have evoked significant public backlash against conservation. In the USA, there have been numerous attempts to repeal or weaken the Endangered Species Act, an Act that was unanimously approved by the US Senate in 1973. As a result of public backlash, the US conservation policy has evolved to rely more heavily on conservation easements, habitat conservation plans, and other negotiated agreements that provide economic incentives for landowners who pursue conservation-friendly practices.

Rather than hurting people's pocketbooks, these policies financially reward landowners through direct payments, tax breaks, or freedom from future additional restrictions if they adhere to certain agreed on practices or restrictions.

People as Beneficiaries of Conservation

Conservation of nature is motivated not just by ethical arguments regarding human-caused extinction; it is also conducted for the explicit benefit of humans. Many people worry that their children and grandchildren might not be able to enjoy large open spaces and see species ranging from large mammals and birds to orchids and butterflies. Conservation has succeeded in protecting vast expanses of land and water from deforestation, overexploitation, and development (Nagendra, 2008). Across the globe, national parks and other protected areas are hugely popular tourist destinations. And despite their sometimes controversial beginnings, these parks often become a source of national pride, clearly beloved by a majority of citizens. Conservation has also aided the recovery of species such as bald eagles, peregrine falcons, and gray whales. Thanks to a ban on dichlorodiphenyltrichloroethane (DDT) (a pesticide particularly harmful to predatory bird species), restrictions on the harvest of whales, and other such limitations on human activities, future generations of people will get to witness these truly awe-inspiring species.

Beyond the aesthetic value of nature, casual observers do not always see links between conservation and human well-being. But such connections abound. Grasslands and coral reefs provide food and income, forests store carbon and regulate water supply, wetlands and mangrove stands protect people from lethal storms. For example, field studies conducted after the Indian Ocean tsunami of 2004 found that shorelines with intact mangrove forests suffered almost no devastation because the trees dissipated the energy of the waves, whereas neighboring shorelines with destroyed or degraded mangroves suffered tremendous human and economic losses (Dahdouh-Guebas *et al.*, 2005). Based on a retrospective analysis of deaths and damages caused by a 1999 super cyclone in eastern India, researchers estimated that every 68 ha of remaining mangrove forest saved one human life (Das and Vincent, 2009).

Moreover, when the economic costs and benefits of conservation are properly assessed, the positives often outweigh the negatives. For example, unsustainable logging practices in the Togean Islands of Indonesia produce silt and sediment that damage coral reefs. The income lost because of the resulting declines in tourism and fishing far exceeds that generated by the logging. In such a case, adopting more sustainable logging practices or even protecting the forest from all logging would be a net win for society. But this is not obvious without a full accounting of the gains and losses caused by logging versus habitat protection (Pabon-Zamora, 2009).

Protected Areas Can Benefit People

Protected areas can be compatible with and even benefit local people. Conservationists have become increasingly interested in the idea of community-based conservation, which can

mean anything from sharing the financial benefits of protected areas with local communities to actively relying on local people to monitor and manage an area's natural resources. This interest is motivated in part by the realization that it is difficult and expensive to guard and manage large areas that are devoid of people. Such places can become targets for poachers and others looking to make money by clearing trees or extracting other natural resources. Parks devoid of people can also become havens for paramilitary groups and illegal activities such as cultivation of drug-producing plants (West and Brockington, 2006). In light of these challenges, conservationists began to realize that it is better to have the local people present and monitoring the situation (Hutton *et al.*, 2005).

Community-based conservation has had some success. In Bolivia, for instance, all of the conservation areas are inhabited by indigenous people and peasant communities, and the success of the nation's protected-area system is due largely to the fact that these people are custodians of these conservation areas (Eguino and Pabon-Zamora, 2009). Indigenous people are often more open to the creation of protected areas on their lands, as long as the areas can continue to provide livelihoods for local communities. At the same time, conservationists are struggling to move beyond merely involving local communities as participants in conservation debates to truly empowering local communities to make and implement management decisions (Brown, 2003).

Another positive is that, on average, protected areas seem to reduce poverty in the surrounding communities. Besides creating a relatively small number of jobs as conservation managers or park rangers, protected areas can attract large numbers of tourists who spend money on lodging, food, guided tours, rentals of vehicles and recreation equipment, and gifts to bring home. Measuring the social impacts of protected areas is difficult because of confounding factors and the fact that protected areas are often associated with centers of poverty that existed before the areas were established. Using data from Costa Rica and Thailand and quasi-experimental matching methods, Andam *et al.* (2010) asked what the socioeconomic outcomes near protected areas would have been if the protected areas had not been established. After controlling for preprotection characteristics associated with poverty and development potential, they found that poverty declined as a result of nature protection. This does not mean that protected areas never produce undesirable impacts on local populations. But at least there is clear evidence that protected areas can increase the well-being of local communities.

Payments for Ecosystem Services

Beyond intrinsic and aesthetic value, many conservationists argue that conservation of nature can improve human health, nutrition, and material prosperity (Daily, 1997; Kareiva and Marvier, 2007). For example, both human and nonhuman species benefit from clean air and water, so conservation efforts to protect environmental health directly benefit people as well. In addition, nature provides highly valuable ecosystem services including timber, fish, protection from storms and floods, and

sequestration of climate-warming carbon dioxide (Millennium Ecosystem Assessment, 2005).

In many cases the people who benefit from the delivery of ecosystem services live far away from the ecosystems that provide them. For example, a large coastal city may enjoy the freshwater and flood control provided by an upstream forest hundreds of kilometers away. Yet the city dwellers may not recognize the benefits that the forest provides, particularly because they seldom pay for them. Given this, the owner of the forest has little economic incentive to protect the ecosystem services provided by the forest, but he or she may have a big economic incentive to clear the land and sell the timber. To remedy this situation, payments for ecosystem services (PES) have been implemented in hundreds of places around the world (Jack *et al.*, 2008). Through PES programs, governments or other parties financially reward landowners for conserving and restoring the flow of ecosystem services.

Costa Rica is home to the longest-standing PES program. Established in 1995, this program has made payments to more than 4000 farmers for reforestation, forest conservation, and sustainable forest management. The Costa Rican PES program recognizes four services: carbon sequestration, watershed protection, biodiversity protection, and landscape beauty for recreation and tourism (Russo and Candela, 2006). Payments are larger for reforestation than for forest conservation. After 5 years of payments, landowners can renegotiate prices, but they are committed to managing or protecting their contracted forests for 15–20 years, depending on whether their activities are primarily conservation or reforestation. The payments are funded through international donations and a nationwide tax on fuel. This PES scheme is widely thought to be one of the most effective in operation, but it is not without problems. For one thing, the prices paid to landowners are not based on any quantification of what the lands actually produce and do not account for different values based on where the land is situated in a watershed.

The largest PES program is China's Natural Forest Protection Program. Between 1998 and 2005, this program distributed more than \$8 billion to peasants and workers to cease logging and to reforest previously logged lands (Liu *et al.*, 2008). The ecological outcomes were impressive – the annual rate of logging declined by more than 40%, the amount of carbon sequestered was 44.1 Tg (one Tg is a million metric tons), and the area suffering soil erosion was reduced by 6%. The carbon sequestered as a result of this program is equivalent to removing approximately 17.5 million cars from US roads. China has also instituted a Grain to Green Program, which compensates farmers for converting cropland on steep slopes back to forests in the Yangtze and Yellow River basins. The farmers are given grain worth \$300–\$400 per year per hectare of farmland converted back to trees. The main aim of the program is restoration of ecosystem function, especially prevention of flood disasters; secondary aims are poverty alleviation and economic development. This program has directly benefited farmers in more than 30 million households, as assessed by household surveys. Many of the farmers have shifted to the construction, transportation, and restaurant businesses.

Both the Costa Rican and the Chinese examples are considered successes, although program evaluation has been

modest at best. In fact, no PES program to date has convincingly demonstrated that it caused the delivery of additional environmental services relative to other possible conservation approaches (Ferraro, 2011). One of the challenges for PES stems from the voluntary nature of these programs. Given a choice, landowners are most likely to volunteer lands that have little potential for other economic activities. Thus the lands that end up being protected by PES might not have been converted to other uses even in the absence of PES schemes. Although these pioneering schemes represent an important new direction in conservation – one relying on financial incentives rather than command-and-control regulations – it is important that future programs be designed to yield measures of their effectiveness (Ferraro, 2011).

Conservation and Poverty Reduction

The relationship between conservation and human poverty is complicated, and debate about this relationship has evolved over time (see Roe, 2008). Adams *et al.* (2004) provide a helpful guide to the range of views that exists within the conservation community. Some view poverty as an issue completely separate from conservation. These individuals feel that conservation organizations must stick to their primary mission of protecting nature. Poverty, food security, and related concerns should fall strictly within the realm of development and humanitarian organizations. Other conservationists see poverty as a constraint on conservation success. After all, a poor person will be more concerned with immediate needs such as food and shelter than with loftier goals of long-term sustainability and biodiversity. Thus, these people see improving economic security as a necessary ingredient for conservation success. A third camp holds the view that conservation should do no harm, or in other words should be careful to not exacerbate poverty as protected areas are established. Finally, a fourth group believes that poverty reduction depends on the conservation of living resources. This view is consistent with a 2005 report to the United Nations concerning strategies to meet the Millennium Development Goals (an ambitious international agreement to, among other things, halve the proportion of people living in extreme poverty by 2015). This report argues that ecology will be the key to relieving poverty for the world's 750 million rural poor (Giles, 2005).

Conservation goals and goals for improving human well-being do often align. For example, deforestation in Tanzania has increased water runoff and caused water shortages such that more than half the population lacks access to safe drinking water and agricultural productivity has been undermined (Madulu, 2002). Proper management of the water-provisioning services of Tanzanian forests could benefit both people and biodiversity. More generally, the world's poorest people and populations, with the lowest food security, stand to benefit greatly from the protection of nature. Although the economies of wealthier nations are not as directly tied to the goods produced by nature, developing nations derive substantial income from naturally occurring building materials, fuel, and food. Forest products and fisheries, looked at as components of national economies, are 5–10 times more

important for developing nations than for European nations or the USA.

Integrated conservation and development projects (ICDPs) are an attempt to simultaneously protect nature and meet the basic needs of humans (McShane and Wells, 2004; Kaimowitz and Sheil, 2007). The idea behind ICDPs is that because extreme poverty is linked to environmental degradation, improving the lives of local people will improve the success of conservation efforts. The approaches used in ICDPs have focused on ecotourism, game hunting, and nontimber forest products to generate income for local people living in or near protected areas (McShane and Wells, 2004). Reviews of ICDPs suggest that many early efforts were unsuccessful (Adams *et al.*, 2004; Agrawal and Redford, 2006). The reasons for the failures include everything from poor project conception (such as unrealistic projections of markets for nontimber products) to civil strife and corruption to poor project management and overly simplistic understandings of both biodiversity and poverty. One example of a successful ICDP is the creation of the Il'Ngwesi Eco Lodge. Cattle rustling, wildlife poaching, and government pressure to subdivide and develop land threaten both the Maasai culture and the wildlife of Kenya (Christ, 2002). Subdivision would have fragmented some of the largest remaining tracts of habitat in Kenya and ended traditional pastoral life for the Maasai. In 1995, the Maasai community at Il'Ngwesi established an eco-lodge and began promoting tourism to the area. Since then, security in the region has improved, income from the eco-lodge is funding the local school, poaching has been halted, thirteen of the region's nineteen large mammals – including the endangered Grevy's zebra (*Equus grevyi*) – have returned to the area, and some wildlife populations have increased by as much as 500% (Christ, 2002). Ecotourism projects do not always turn out so well, but this example demonstrates how conservation and human interests can sometimes be aligned.

Conclusion

The relationship between conservation and people is complex and dynamic. The negative consequences of an enormous, rapidly growing, and increasingly prosperous human population are why conservation is needed. In response, conservation is a grand intervention in both the natural world and human society, the goals of which largely reflect human likes and dislikes. Conservationists may seek to modify or prohibit certain economic activities, and conservation has at times caused relocations of human communities, disruption of traditional resource management practices, and job loss. Although conservation has earned a reputation in some circles of valuing nature above people, conservation also provides profound benefits to people by protecting open space, magnificent wildlife, and ecosystems that provide invaluable services for both current and future generations. Conservation attempts to improve environmental conditions for the benefit of both human and nonhuman species, and it seeks to increase the sustainability of resource use so that the prosperity and health enjoyed by today's human population may continue into the future. In light of criticisms regarding the uneven distribution of harms and benefits across human groups,

conservationists are becoming more sensitive to the rights of human communities and are developing new approaches that aim to better advance the well-being of both people and nature.

Glossary

Ecosystem The community of organisms in a defined area combined with the physical factors of the environment with which the community interacts.

Ecosystem goods Commodities, such as timber and seafood, supplied free to humanity by natural ecosystems.

Ecosystem services Functions, such as flood control and pollination, supplied free to humanity by natural ecosystems.

Introduction

Ecosystems are the functional units composed of the elements of biodiversity (plants, animals, fungi, and microorganisms) in a specified area interacting with each other and their non-living environments. Ecosystems are the “natural capital” that generates a flow “interest” in the form of ecosystem goods and services that are essential to civilization. Natural ecosystems have been the source of all foods consumed by human beings, a large proportion of the medicines, and many important industrial products ranging from natural dyes to cotton and timber. In addition to those ecosystem goods, ecosystems also supply a wide array of ecosystem services. Among other services, ecosystems tend to buffer against sudden changes in the climate, control the hydrologic cycle that brings freshwater, control floods, generate and maintain fertile soils, dispose of wastes and recycle nutrients, pollinate crops, and control the vast majority of pests that would attack crops or carry disease to human beings.

Human impacts on ecosystems precede the dawn of history. Discernable impacts probably began when people (quite possibly *Homo erectus*) first began to use fire as a tool in hunting, but there are almost insurmountable difficulties in determining when that was – perhaps more than a million years ago, perhaps as recently as 50,000 years ago. The skill of modern *Homo sapiens* as hunters is attested to by their probable role in the extermination of the so-called megafauna near the end of the Pleistocene epoch (ice ages starting about a million years ago) – mammoths, cave bears, giant sloths, and the like. In dramatically changing the structure of communities of large animals, many of which were herbivores (plant eaters), they thereby substantially altered plant communities and thus modified entire ecosystems. It was the agricultural revolution, some 10,000 years ago, however, that paved the way for the large-scale impacts that threaten the integrity of ecosystems (and thus of the critical services they supply to humanity) today. Indeed, early agricultural activities seem likely to have initiated the climate disruption that so threatens ecosystems today. In the past 150 years, since the Industrial Revolution hit its stride, the scale of the human enterprise (as measured by overall energy use) has multiplied

roughly 20 times, as a result of a fourfold increase in population size and a fivefold increase in *per capita* consumption. This, of course, has resulted in a roughly 20-fold increase in the impact of *Homo sapiens* on ecosystems.

Current Impacts

The result of this expansion is that humanity has become a global geophysical force, altering Earth on a scale as large as or larger than forces such as volcanism, erosion, natural oil seepage into oceans, and, especially, the natural extinction of populations and species of nonhuman organisms. Humanity has now altered every cubic centimeter of the biosphere, at the very least by changing the climate and distributing synthetic organic chemicals, novel radionuclides, and particulate matter globally. Humanity’s modification of ecosystems has been primarily mediated through its effects on their living elements.

Habitat Alteration

The most significant way in which people influence ecosystems is by degrading the habitats required by nonhuman organisms. Often this occurs simultaneously through a variety of channels, so that the types of degradation discussed later overlap with one another.

Deforestation

Forest destruction is probably the most widely recognized form of ecosystem degradation, since it so rapidly and dramatically transforms the structure of the habitat. In the past few centuries, about one-half of all tropical moist forests have disappeared, and in southeast Asia, much of the lowland moist forest is already gone. Large areas of temperate forests have been cleared, but in some areas (such as the USA), there has been substantial regrowth. Many ecosystem services are degraded by deforestation, including flood control, maintenance of appropriate gaseous content in the atmosphere (especially through carbon sequestration), regulation of the climate in other ways, control of vectors of disease, and provision of timber. Reduction of populations of dangerous

predators such as tigers is a rare and debatable benefit to *Homo sapiens*.

Forest Fragmentation

The growing patchiness of forests is receiving increasing attention, since brute rates of deforestation underrate the ecosystem impact of deforestation for a number of reasons. First, fragmentation leads to a loss of species diversity due to species-area effects. The number of species that a parcel of habitat can maintain is generally a function of its area. In general, 10 fragments averaging 1 km² each will retain less diversity than a single fragment of 10 km². Second, fragmentation increases the amount of forest edge relative to forest interior, making forest interior organisms more vulnerable to edge-specializing predators. For example, there is some evidence that predation on the eggs of ground-nesting temperate forest birds increases with proximity to edge. Third, fragmentation, especially of tropical moist forests, may lead to further forest destruction because of the penetration of winds and drying into much of the interior of small patches. Fourth, fragmentation can lead to secondary extinctions resulting from the loss of biotic interactions. For instance, extermination of populations of required pollinators can lead to the loss of plant species still present in the fragments; loss of army ants from a too-small patch can cause the disappearance of obligate ant birds. And fifth, loss of species from the fragments due to inbreeding depression (loss of genetic variability leading to lowered fertility or other deleterious effects) or chance (stochastic) extinctions stems from the small size of residual populations.

Selective Harvesting of Forests

Highgrading is the removal of commercially valuable species while bypassing others; it can dramatically alter the taxonomic composition and structure of forests. Removal of mahogany trees is a classic example; so is removal of key understory elements, such as the rattans now being extracted from the forests of southeast Asia.

Fire Suppression

Intervention to prevent fires in forest and chaparral ecosystems that normally burn periodically, known as fire suppression leads to a buildup of fuels that eventually can result in uncontrollable, extremely hot fires that change the entire system by killing organisms that would ordinarily survive the smaller, cooler fires characteristic of the original fire regime.

Conversion to Farms

Clearing of natural ecosystems to introduce crop agriculture normally results in the near-total destruction of the ecosystems. Virtually all of the larger native plant and terrestrial animal species are directly extirpated, and many of the smaller plants and animals (e.g., insects, reptiles and amphibians, birds and bats) go to extinction because of loss of habitat and changes in the microclimate.

Conversion to Grazing

Conversion of natural ecosystems to grazing can be as destructive as or more destructive than crop agriculture if, for example, large areas of tropical moist forests are cleared to make pastures. If, on the contrary, a savanna ecosystem with

abundant natural grazers simply has the composition of the grazing community changed (as when small numbers of cattle are added to the ungulate population of an East African savanna), the damage can be much smaller. Nonetheless, at a minimum the composition and structure of the flora are altered by the introduced herbivores, and often attempts are made to control potential predators on the grazing animals, which may also have cascading effects on the original flora and fauna.

Conversion to Infrastructure

Building structures, highways, malls, and so forth competes with farming to have the greatest impacts per unit area on natural ecosystems. At best, only disconnected fragments of the original system remain, and the delivery of ecosystem services is almost totally disrupted. Conversion to infrastructure, with its destruction or covering of the soils that are normally essential to maintaining a terrestrial ecosystem, is one of the most irreversible forms of human impact on ecosystems (although in the absence of maintenance, altered but "natural" ecosystems will eventually recapture human-modified systems). Division of habitat by roads is also a form of conversion to infrastructure. Roads cause impacts on ecosystems far more than those created by the road-building itself. First, they may form barriers to the normal movement of animals. Second, they serve as conduits for the introduction of invasive organisms. Third, dirt roads may influence the flora and fauna of adjacent areas by deposition of dust (which, for example, functions as an insecticide). And fourth, especially in tropical moist forest areas, they increase penetration, settlement, and recreational use by human beings, all of which generate additional impacts.

Mining

Extraction of minerals varies in its ecosystem impacts, depending on the scale of the mines, whether they are underground, open pit, or placer (hydraulic/washing/dredging) operations, and the material mined. Large-scale open-pit mining tends to be totally destructive and expensive and difficult to ameliorate. Underground mining usually has less impact, but can destroy aquatic systems over large areas through the runoff of toxic drainage from the mines and can convert terrestrial systems into "slime pits" for mine wastes.

Damming and other Water Development

Human attempts to intervene in the hydrologic cycle has massive impacts on the ecosystems of rivers and streams by changing water flow patterns and temperatures and blocking the movements of anadromous fishes (ones that breed in streams but spend much of their lives at sea). Conditions may be created that encourage the spread of disease, as in the increase of Bilharzia in Egypt after the building of the Aswan High Dam. The dam made possible irrigation canals that were ideal breeding grounds for the parasitic worms that cause the disease. Terrestrial ecosystems, of course, are directly destroyed by inundation.

Wetland Drainage

Drying of wetlands eliminates the organisms and services supplied by estuaries, marshes, and bogs (flood control, water

purification, nursery services for commercially important fish species). Loss of wetland habitats also disrupts the migratory patterns of birds and reduces their food supply, including wildfowl valued by hunters.

Siltation of Onshore Ocean Waters

A flow of silt into the oceans results from timbering operations, construction, and other human activities in coastal zones. Siltation leads in the tropics to the destruction of coral reef ecosystems by smothering the coral organisms. This in turn leads to the loss of local fisheries and ecotourism opportunities.

Toxics in Aquatic Systems

Toxification of onshore ocean waters, lakes, and streams may disrupt marine ecosystems and negatively impact fish populations (by direct poisoning or indirectly by eutrophication – overfertilization of the water bodies by nitrogenous runoff from agriculture and urbanization). Toxins may also render fish unfit for human consumption, disrupting the food supply service of aquatic ecosystems. Agricultural runoff and sewage dumping have converted many areas of the oceans into “dead zones” in which oxygen levels are so low that most animals cannot live in them. Toxification, which has influenced the entire planet from pole to pole, is one of the most subtle forms of habitat alteration. Often toxic substances are active in concentrations that are difficult to detect, especially when they function by mimicking hormones that influence the early development of animals. The long-term ecosystemic effects of the adding of tens of thousands of synthetic organic chemicals to the global environment are simply unknown.

Ozone Depletion

Thinning of the ozone layer adds another toxic substance to Earth’s ecosystems – an increased flux of dangerous ultraviolet B radiation (UV-B). The impact of such radiation can be judged from the fact that until some 450 million years ago, life could not exist on the land surface because there was no ozone layer to screen out UV-B. Until then, organisms had sheltered in aquatic ecosystems, because water rapidly reduces the UV-B flux. Ozone depletion has been most serious in the region of the “ozone hole” in the Antarctic, where impacts on oceanic ecosystems are already reported. As with other toxic substances, the long-term effects of moderate ozone depletion are difficult to predict. It has been postulated that increased UV-B or other toxic materials are involved in a global decline of amphibian populations, but the data are still too fragmentary to permit definitive judgments to be made.

Recreation

Recreational activities have diverse impacts on ecosystems. Off-road vehicles compact and erode soils and kill organisms that burrow in them, being especially destructive in arid climates. Trails in parks can cause local erosion and disrupt the normal activities of wildlife. Boat anchors and scuba-diving activities contribute substantially to the destruction of coral reefs in some localities. Ecotourism, which can provide economic benefits for conservation, can also be destructive if not properly controlled. Outflow of sewage from coastal hotels pollutes the waters of offshore reefs. Disturbance to

animal communities and the native flora by tourist vehicles and lodge garbage in some African game parks is another example of the negative effects of ecotourism.

Climate Change

Alteration of the climate, which may be induced or accelerated by human activities, is a major mechanism for disrupting ecosystems. Global warming is clearly changing both terrestrial and aquatic ecosystems in the boreal regions. Perhaps the most serious immediate threat is thinning of the sea ice in the Arctic, which may lead to ice-free summers in the Arctic Ocean by 2050, if not sooner. Loss of the summer ice pack will have large, if difficult to predict, consequences for polar bears and other aquatic mammals and the food chains in which they participate. But the greatest threat of broad-scale ecosystem impacts likely resides in the potential for changing patterns of oceanic currents. Should, for example, the Gulf Stream fail or be deflected, all of the ecosystems of Western Europe would be severely stressed, to say nothing of the human populations there.

Anthropogenic climate change could be many times faster than the relatively rapid natural changes (probably enhanced by the spread of agriculture) that occurred following the last glaciation. It would certainly cause large-scale population extinctions in some areas. Changes in range and some local population extinctions have already been detected in butterfly species in western North America and Europe. Changing climates might also lead to a substantial loss of species diversity. Much will depend on the speed and nature of the changes, the genetic attributes of organisms and other species with which they are coevolving, and the capability of organisms to migrate past extensive barriers created by near-ubiquitous human development.

Alien Invasions

Alien invasions are little appreciated as engines of ecosystem modification, and yet they are one of the most important.

Islands

Many oceanic islands have lost most of their native floras and faunas to species transported by *Homo sapiens*. The destructive invaders include goats (which long ago played a major role in transforming the ecosystems of the Mediterranean basin), rats, mongooses, Philippine brown snakes (which devoured most of the avifauna of Guam), and mosquitoes (which carried bird malaria to Hawaii, resulting in the extinction of almost all species of native birds).

Continents

Continental ecosystems have also been highly modified by invasions. Most of the grasslands and woodland savannas of California are now nearly devoid of native herbaceous plants, having been substantially taken over by introduced annual grasses and herbaceous weeds from Europe.

Onshore Waters

Not only has the flora of California been greatly modified by exotics, but the coastal waters, especially around the

San Francisco Bay, are also host to a myriad of invaders. Many of these arrived in the ballast water of ships arriving from all over the world. One, the eastern shipworm, was tolerant of the relatively dilute sea water of the bay, as the native western shipworm was not. After it was introduced early in the twentieth century, it proceeded to destroy the wooden piers and bridges that laced the bay, doing as much financial damage as the 1906 earthquake.

Disease Organisms

Pathogens moved about by human beings also greatly influence ecosystems. A classic case was the introduction of a virus disease of ruminant animals, rinderpest, into northeast Africa around 1884. The disease raced south, reaching South Africa in 1896. It not only decimated the cattle herds of peoples like the Masai (causing severe famines), but also infected giraffes, buffalo, and wildebeest, causing a die-off that led to starvation of their natural predators. One consequence was that lions switched to eating people, so farmers deserted their land. In the absence of farmers and native browsing animals, brush and woodlands invaded grasslands, altering the entire ecosystem. Some resistance developed in the animals, and the situation has fluctuated since, with rinderpest remaining a factor in east African ecosystems. More recently, a fungal disease of bats, white-nose syndrome, has killed millions of the tiny mammals in North America, threatening the pollination and insect control services that bats supply.

It is speculated that the fungus was imported from Europe, but this remains unclear.

Overexploitation of Ecosystem Components

Habitat alteration and invasions are not the only ways in which human activities produce impacts on ecosystems. Another important pathway is overexploitation of economically desirable organisms, which in turn alters habitats.

Food

Often overexploitation occurs when natural populations are harvested for food. A classic example was the persecution of the passenger pigeon, which once was the most abundant bird in North America. One flock was estimated to contain 2 billion birds. Flocks moved around, breeding when large crops of beechnuts, acorns, and other forest nuts were found. They were commercially hunted to extinction to supply food markets in eastern cities, the last individual dying in the Cincinnati zoo in 1914. It has been suggested that their absence altered eastern forest ecosystems and greatly increased the food supply of rodents involved in the cycle of Lyme disease. If true, the ecosystemic effect of their extermination had an impact on humanity beyond the loss of a once abundant and easily harvested source of animal protein.

Fishing often alters ecosystems by disrupting normal oceanic food chains, especially when there is overfishing and when there is heavy "by-catch." According to new estimation methods, some 7 million metric tons of marine life are killed and discarded by oceanic fishing fleets, equivalent to about a tenth of the total catch retained, and this does not account for the heavy local mortality caused by dynamite and cyanide

fishing on coral reefs. Increasingly, trawls dragged along the bottom are destroying the biotic structure there, with unknown future consequences.

Natural Products

The demand for natural products can also lead to overexploitation with accompanying ecosystem alteration, as discussed under forest clearing and fragmentation above (*see* Forest Fragmentation). But it is often difficult to measure the impact, for example, of the harvesting of specialty woods by "highgrading." Again, far more damage to the forest is sustained by the building of roads, the associated felling of nontarget trees, and the transport of harvested trunks by "skidding," than the small amount of damage from the selective removal of valuable hardwoods. Similarly, although the demand for turtle shell and soup has had serious consequences for turtle populations, little is known about the ways oceanic ecosystems may be altered by the reduction of turtle populations.

Esthetic Resources

The demand for pets frequently leads to the overexploitation of natural populations. Some of the cyanide fishing on coral reefs is aimed at aquarium fishes rather than those sold to grace the plates of rich Hong Kong businessmen. Freshwater tropical fishes are also often overexploited for the aquarium trade. The ecosystem changes being caused by the latter have not been seriously investigated. The pet bird trade has large-scale impacts on some species and in some regions. It is so popular in Indonesia that songbirds are virtually absent from much of Java due to trapping (and overuse of pesticides). In the Pramuka bird market in Jakarta, some 60,000 individuals and 160 species once were for sale in a given day. But even the impact of bird removal on the insect populations of Java is not known, let alone the overall (or long-term) ecosystemic consequences. The story is similar for the removal of giant saguaro cacti in Arizona or the poaching of orchids, chameleons, and geckos around the world – biologists realize the ecosystems are being altered, but there is neither the time nor the personnel required to evaluate these and many other impacts.

Scientific and Educational Use

Finally, sad to say, some organisms are overexploited for scientific and educational purposes. A classic example is the northern leopard frog, *Rana pipiens*, which once was abundant and harvested in large numbers for use in dissections in high school and college biology courses. It is now a rather scarce organism, in part because of overharvesting.

Signs of Ecosystem Deterioration

If humanity is causing substantial impacts on ecosystems, can one detect what they are? In many cases, the answer is yes, although precise measurements are difficult to obtain, mainly because baseline measurements were never taken before impacts occurred. Most, if not all, of the observed and measurable impacts are negative; positive changes have been observed largely in cases where the pressure has been lightened (e.g., the recovery of forests in parts of the eastern US after failing farms were abandoned).

Perhaps the most direct way to measure ecosystem deterioration is to measure the biological productivity or net primary productivity (NPP) of an area, if possible over time. If an area is converted from a natural to a human-directed system (forest to pasture; meadow to farm fields), NPP usually falls. A further decline in NPP (for instance, crop yields) over time indicates deterioration. Such declines, even in the face of increased fertilizer applications, have been widely observed, and it is well known that fertilizer applications can mask losses of micronutrients from soil and declines in soil structure for considerable periods before declining productivity becomes apparent. In such situations, not only is crop or forest productivity lost, but also the ecosystem services of soil replenishment and nutrient/waste recycling (which are also a vital part of the planet's biogeochemical cycles that control the distribution of nitrogen, oxygen, carbon, and water, among other critical substances) are also usually damaged.

Faltering Food Production

This may be the most significant trend in which human impacts on ecosystems play a role. Since 1984, the global grain harvest has failed to increase significantly on a *per capita* basis. Since cereal grains – primarily wheat, maize, and rice – make up more than two-thirds of the human feeding base and equal in weight at least half of all foodstuffs produced by agriculture, trends in grain harvests are the best indicators of food supplies and availability. There are, unfortunately, signs that climate disruption is already limiting the increase in grain production. In addition to ecosystem impacts, economic factors and changes in eating habits are also important in determining sufficiency. More than a third of the world grain harvest is used for feeding livestock today, and a growing fraction in recent years has been diverted into biofuels (including nearly a third of the grain crop in the USA by 2010). Shortages in grain supplies for human food could be somewhat compensated by reducing its use as feed or biofuel, although the higher prices commanded by biofuels make it unlikely that its feedstock will be diverted.

Tight supplies of grains often cause rises in price on the global grain market, which in turn cause prices of meat and other animal products to rise and consumer demand for them to fall. Reduced demand for animal products naturally leads to reduced demand for feedgrains, and vice versa. In industrial countries, more than half the grain consumed is used for feed, whereas in developing nations, by contrast, most grain is directly consumed by people. In the USA, demand for animal products has shifted away from beef to poultry, which can be grown with about a third as much grain per pound of meat produced. But in some developing countries, especially China, demand for animal foods is rising rapidly, and consumption of feedgrains has risen accordingly.

Despite these shifting economic and consumption patterns, the overall trend of food production has been increasingly problematic in recent years, with aggregate production barely managing to keep abreast of population growth, even though that growth has slowed markedly in the past two decades. Food production in sub-Saharan Africa, where populations are still growing rapidly, has fallen especially far behind.

The reasons for the slowdown of food production increases are many and vary from area to area. They include the Green Revolution running out of steam, diminishing returns from fertilizer applications, the decline in genetic diversity of major crops, the continuing loss of prime farmland to urbanization, soil erosion, salinization (land degradation from poorly managed irrigation), desertification, and water shortages, often from depletion of aquifers. Among problems of rising importance are underlying trends of land degradation and the related loss of ecosystem services. Although potential food production has kept up (marginally) with population growth, following are the key issues: (1) how much higher would that potential be if important ecosystem services had been carefully conserved and if climate disruption had not begun to be a factor and (2) can humanity depend on linear extrapolations of twentieth century production trends over a 50-year timescale?

Of ecosystem services that are being impaired or lost, some are basically local – soil erosion and depletion, loss of natural pest and crop disease controls, and loss of pollination services. Others are regional, such as the consequences of damage to nearby watersheds. Thus, deforestation of a watershed area leaves adjacent or downstream areas more vulnerable to floods and droughts. The destruction by unprecedented floods of a substantial portion of the agricultural capacity of Pakistan in 2010 is a case in point. There also is evidence that maintaining natural areas interspersed among intensively farmed areas helps to preserve soil fertility as well as providing sources of natural pest control, pollinators, and impediments to the spread of crop diseases.

The Green Revolution, along with agricultural expansion, a dramatic increase in irrigated lands, and other favorable factors, allowed grain production to rise by more than 73% from 1960 to 1980, whereas the population expanded by 46%. But from 1980 to 2009, grain production increases fluctuated, barely keeping pace with population growth. Up to 1984, grain production increases had exceeded population growth, reaching a *per capita* peak then of 342 kg; since then it has fluctuated between 300 and 340 kg *per capita*.

The degree to which human impacts on ecosystem services are involved in the difficulties of agriculture is hard to evaluate. Some crop damage by pests is clearly due to diminution of natural pest control services, but pesticide use (a major culprit in the destruction of natural pest control) and cultural practices make up for some of that loss. Similarly, declines in natural pollinator services are known to be occurring, but crop failures due to lack of pollination are few, since managed pollinators (generally honeybees) are often brought in to do the job. Honeybees themselves are at risk, due to exotic diseases, loss of floral resources that support honeybee colonies, and pesticide use. Loss of flood control services, due primarily to deforestation of watersheds, often results in serious damage to crops in places as diverse as the Indian subcontinent and Central America. Soil loss to erosion – perhaps 25 billion tons annual more than soil regeneration – also reduces agricultural production. And anthropogenic modification of ecosystems is depleting the genetic library of crop relatives and crop biocontrol agents, which are all critical to maintaining crops in their coevolutionary races with diseases and pests.

It is important to remember that agriculture is largely dependent on the weather and that climate stabilization is an important service of ecosystems. Thus, for example, the severe damage to agriculture due to a massive heat wave in Russia, and huge floods in China and Pakistan in 2010, may have been exacerbated by a decline in this service if anthropogenic global warming played a role in intensifying those unusual weather events. Changing trends in weather, including floods, droughts, and changes in the timing of seasonal warming or rainfall, will inevitably have major impacts on agricultural production around the world. Indeed, climate change has been shown to have reduced global harvests of wheat and corn by about 5% and 4%, respectively, from 1980 to 2008.

Fisheries Decline

Fisheries yields tell an even more dismal story – and at sea there is no doubt that yields have not been keeping pace with demographic expansion. Some 80% of the world's major fisheries are depleted or are being maximally harvested today. A peak in fisheries yield was reached in 1988 at 17.2 kg *per capita*, but yields have since remained below that level. Most of the blame for declining yields can be put on overharvesting, yet more systemic environmental damage has also played a role through the pollution and modification of estuaries and coral reefs, the destruction of mangrove fringes and coastal wetlands, the creation of dead zones through eutrophication, and the devastation of sea-floor communities by repeated benthic trawling. Anadromous fish (such as salmon) have suffered from damming of rivers and oversilting from bank erosion. Major oil spills have taken a toll on seabirds, marine mammals, and shellfish, causing lingering damage to coastal fauna in many areas.

With fisheries yields roughly stagnant for more than 20 years, growing dependence on aquaculture (fish farming) harvests has met demand for seafood. By 2010, fish farming was contributing nearly half of the seafood produced globally. But aquaculture causes new pollution and habitat destruction problems that impact natural fish populations, and fish farms rely extensively on fish products for feed. Thus, they tend to produce a net loss in fish biomass. They also are creating a rising demand for feedgrains and other agricultural products to support their yields, thus competing, along with livestock operations, with human beings for the food they raise.

It is not clear how much sustainable production of food by terrestrial agriculture is being reduced now by overexploitation and ecosystem modification. Genetic improvement of crops and increased use of water and fertilizers (among other technological advances) allowed rather consistent increases in production over the last half of the twentieth century. Despite the heavy promotion of genetically engineered crops, their introduction has not resulted in significant increases in harvests. More often, the gains were in pest control without use of toxic chemicals and in the development of such crop traits as resistance to drought or salt buildups in soil.

Important questions for the future include the following: How much more production in the past (and in the near and long-term future) would have been possible if more care had been taken to protect ecosystem services? How sustainable is the present agricultural production system, given that land

degradation continues and the availability of sufficient water seems increasingly problematic as demand keeps rising and watersheds are being compromised by melting glaciers and snowpacks and changing rainfall patterns due to global warming? In addition, depletion of petroleum reserves is likely to lead to higher costs and shortages of fertilizers and pesticides. It is clear that, to meet the continued increases in demand for food by a growing human population and to meet them sustainably, agricultural production methods must undergo a different type of “green” revolution – one that more closely mimics and harnesses the natural processes in natural ecosystems.

Change in the Epidemiological Environment

This may be another sign of ecosystem modification. Anthropogenic ecosystem changes and greenhouse gas emissions from burning fossil fuels are clearly threatening the deterioration of the climate stabilization service. Those changes may have played a role in the warming that has caused dengue fever to move northward in North America, for example – and warming has been predicted to have similar effects on malaria and other tropical diseases.

Decline in Water Quality

Increasing water pollution is often a direct reflection of modification of ecosystems. A classic example is that of the New York City water supply. Around 1900, New York City's water was of such high quality that it was bottled and sold throughout New England. A century later the EPA notified the city that its water had dropped below acceptable quality. The reason was changes in the ecosystem of the Catskill Mountain watershed that served the city. Fertilizer runoff and inadequate local sewage treatment had impaired the natural-water-supply service. It was estimated that constructing a plant to treat the Catskill water would have a capital cost of \$6–8 billion, with roughly a \$300 million annual maintenance cost. In contrast, restoring the functioning of the natural Catskill ecosystem would cost only \$1–1.5 billion. New York made the obvious choice and provided a classic case of ecosystem modification and the loss and restoration of ecosystem services. The New York City case is now being emulated in many parts of the world.

Other Symptoms

There are, of course, many other readily observable symptoms of anthropogenic ecosystem deterioration, some of which have already been mentioned. On land they include flooding, landslides and heavy soil erosion, changes in microclimate, the local disappearance of sensitive species of plants and animals, siltation of streams, and lowered water tables. A general decline of amphibians that seems to be occurring over much of the world suggests ecosystem disruption from multiple causes. In oceanic systems, changes in the mix and abundance of large animal and plant (e.g., kelp and sea grass) and planktonic species are also observable and often, as in cases of algal blooms or precipitously declining fisheries yields, are signals of serious disruption.

Driving Forces

The impacts of human beings on ecosystems are a product of three multiplicative factors: population size, affluence (or *per capita* consumption), and the technologies and social-political-economic relations that supply the consumption. These relationships are often condensed for convenience into the equation $\text{Impact} = \text{Population} \times \text{Affluence} \times \text{Technology} = I = P \times A \times T$, the “IPAT equation.” If one uses *per capita* energy consumption as a surrogate for $A \times T$, the result is that quoted in the start of this article – a 20-fold increase in human impact on ecosystems in the past 150 years.

Overpopulation and Continued Population Growth

Population growth is probably the single most important factor leading to impacts on natural ecosystems. Early in the nineteenth century, there were only 1 billion people. That number had doubled to 2 billion around 1930, doubled again to 4 billion in 1975, reached 6 billion in 1999, and 7 billion in 2011. It took on the order of 300,000 years for the population of *Homo sapiens* to reach a billion, a single century to add the second billion, 30 years to add the third billion, 15 for the fourth, and 12 each for the fifth, sixth, and seventh.

Simply adding so many people to the population required gigantic alterations of natural ecosystems to bring sufficient land under cultivation to feed them and further destruction as agriculture was intensified in the past century or so. This effect was exacerbated because each individual added to the population tended to generate a disproportionate ecosystemic impact. Naturally, people farmed the most fertile soils first, got their water from the nearest sources, mined the most concentrated ores, and so on. More people required the farming of more marginal land, leading to increased land degradation. The transportation of water over greater distances involved using more water per person to make up for losses in storage and transport, and the disruption of more land per person with dams and other infrastructure. The mining of poorer ores meant that more ecosystemic destruction by mining was caused per person, since more ore must be dug up to provide the same level of metal use for each additional individual.

Since at least 1950, the entire world clearly has been overpopulated by the simple standard that the human population could not be sustained by the flow of resources generated by incoming sunlight mediated through farms, forests, the hydrological cycle, and so forth – the agricultural and natural ecosystems of Earth. Instead of preserving humanity’s “natural capital,” it has been necessary to expend it. Three elements of that capital are especially important. The first is deep rich agricultural soils that are generated on a timescale of centimeters per millennium and are now in many areas being destroyed at a rate of centimeters per decade. The second is aquifers, many of which were last filled during the ice ages and which are now in many, if not most, areas of the world being pumped at many times the natural recharge rate. The third is biodiversity, the species of microorganisms, plants, and animals that are working parts of ecosystems, which is now being exterminated at a rate unprecedented in the past 65 million

years – at perhaps 1000 times its rate of natural regeneration from speciation.

Furthermore, the high rate of additions to the human population in the second half of the twentieth century meant that little concern could be shown for the possible long-term effects of the interventions designed to keep people eating. Programs such as the Green Revolution were driven in part by fear of massive starvation, and their consequences for natural ecosystems and the vital services they provide were largely ignored. So were their social impacts.

Overconsumption

Overconsumption is almost as important as overpopulation as a driver of ecosystem modification. For example, a significant proportion of the ecosystem modification caused by the agricultural enterprise is created by growing grain and feeding it to animals destined for human consumption. This is the case even though in rich societies, consumption of products containing animal fat (and, perhaps, overconsumption of animal protein) is a serious public health problem. The directly toxic and hormone mimicking effluents from the production of myriad products, many of them plastic or packaged in plastic, also are undoubtedly having effects on ecosystems, although data beyond changes in single species are lacking. But one of the most serious overconsumption problems derives from converting societies to dependence on the automobile, combined with the marketing and purchase of cars much too large, heavy, and inefficient for the purposes to which they are put.

Use of Environmentally Malign Technologies

The use of technologies that are unnecessarily environmentally malign is related to overconsumption. The use of inefficient automobiles is echoed in the use of unnecessarily inefficient lighting, heating, appliances, and so on. But the basic technological problem in society at the beginning of the twenty-first century is the persistent overdependence on fossil fuels, and especially coal, as an energy source.

Faulty Economic Arrangements

Market failures are partly to blame for the overdependence on fossil fuels, because the market prices of those fuels do not come close to reflecting their social costs. For example, the costs incurred by society in the form of lung disease from the effluents caused by fossil fuel burning are not factored into the market price, neither, in the USA, are the costs of maintaining large military forces designed to ensure a steady flow of oil into the American economy. More importantly, the present and potential costs to society of climate change induced by carbon dioxide emissions from fossil fuel use are also not factored. If these and other social costs, such as pollution due to oil spills and discarding of lubricants used in automobile maintenance, other emissions, and medical costs deriving from automobile accidents, were captured in market prices, the price of gasoline in the USA might be quadrupled.

Faulty Social Arrangements

Social arrangements often work against the protection of ecosystems. For instance, society has not designed educational systems to apprise its citizens of the biophysical and social realities that it faces. Few people, even “well educated” people in rich societies, can provide a coherent explanation of ecosystem services or the threats to their delivery. Indeed, there is a general failure of the media and standard educational systems to make explicit connections among the many factors and effects of human alteration of ecosystems.

Faulty Political Arrangements

Political errors also play a substantial role in endangering ecosystems. Societies generally lack “foresight” institutions that have the capacity and independence to analyze complex problems and provide competent and independent advice to government and the general public. In addition, there is the age-old problem of disparities in power, which now has increasingly widespread – often global – implications for the sustainability of society. Powerful supporters of politicians in Rome were hard-pressed to weaken the Empire. Today’s business interests pressing politicians through campaign contributions and lobbying in the USA, or in other ways elsewhere, to take no actions to ameliorate global warming theoretically could bring down civilization.

Solutions

In light of the myriad uncertainties about both human and ecosystem behavior, it would seem prudent to try to reduce the three factors in the IPAT equation simultaneously, rather than risk a possible catastrophic collapse of services as *Homo sapiens* progressively alters natural ecosystems. What sorts of steps might be taken to avoid such a collapse? Some are proximate – steps that would directly address impacts on ecosystems. Others are ultimate – steps that would deal with the basic drivers of ecosystem deterioration.

Proximate

A nonexhaustive list of proximate steps might include the following:

1. Limit development so that a maximum of the remaining relatively undisturbed ecosystems would be preserved. In virtually every country where new infrastructure is needed, it should be provided as far as possible by intensively redeveloping areas that are already highly disturbed.
2. Rapidly implement agreements and measures to slow climate change, despite the serious political and economic difficulties of so doing. It is entirely in the interest of affluent countries to assist the poorest countries to develop and deploy from scratch energy systems that do not depend on fossil fuels.
3. Establish and protect reserves designed to protect relatively undisturbed ecosystems and the elements of biodiversity they contain. This should be done only when it is possible

to integrate the interests of local people into the reserve design – otherwise in the long term the effort is likely to be wasted as population growth pushes people increasingly into reserves that they do not value as such.

4. Limit toxic releases by shifting the burden of proof to those who would claim that the introduction of a novel compound into use (and thus into the environment) carries benefits that clearly exceed the social costs. And reexamine the ~65,000 compounds that have been “grandfathered” as safe for release without any real evidence, just in the USA.
5. Enforce sustainable-yield harvesting for all living resources. Harvesting systems should be designed with substantial attention to the precautionary principle (erring on the side of conservatism), in order to buffer society against the consequences of overoptimistic estimates of what is sustainable.
6. Game ranching is, in some circumstances, able to maintain the diversity of grazing ecosystems much better than a monoculture of cattle or sheep. Problems of game ranching can include public acceptability of the meat, high prices, and conflict with cultural values associated with traditional grazing routines. In one case, on the Athi plain of Kenya, near Nairobi, a game ranch led to restoration of the land and profits from the meat of a variety of antelope species (with different grazing and browsing methods). That, despite resistance from traditional Masai cattle grazers and a bureaucratic prohibition from marketing hides.
7. Apply principles of countryside biogeography. Countryside biogeography is the field that is developing principles for making already disturbed areas most hospitable for biodiversity and thus more likely to provide necessary ecosystem services. One step in doing this would be to pass (or strengthen) laws to protect endangered populations, species, and landscapes and to restore moderately degraded areas, including restoration with useful, native species
8. Develop nonfarm and urban area management regimes that allow for maximal adjustment to changing climates by floras and faunas. This would include keeping possibilities open for migration of animals and plants through wildlife corridors and other mechanisms.

Ultimate

Steps to deal with the ultimate drivers of ecosystem deterioration mean dealing with the factors of the IPAT equation:

Population Reduction

Population growth should be halted as soon as humanely possible, and a slow decline initiated toward a level that can be sustained indefinitely at whatever average level of consumption is selected. Selection of that level, which is closely related to the issue of optimum population size, need not be debated in the near future. That size will change with available resources, technologies, and preferences. The human population is already well above the long-term carrying capacity, so a goal of gradually and humanely reducing population size is likely to be valid for at least a century. Until then there will be

abundant time for scientific study and social debate over the level at which to stabilize human population. Human beings, as far as can be known, have at times and in some places altered vital rates and adjusted population sizes to needs perceived primarily through the economic situations of reproducing couples. In recent decades, there has been a shift to substantial consideration of the needs of society as well, and that trend should be accelerated in the future.

Consumption Control

Controlling consumption will be a more difficult task than controlling population growth, if current trends and attitudes are any guide. This is an area fraught with difficult issues of equity and feasibility. For instance, if the gasoline tax in the USA were raised to the point where gasoline was as expensive as in Europe, a substantial decline in fuel consumption would be likely. But there would be a deleterious impact on poor people that must commute to work by car. Compensatory tax changes would be needed to lighten that burden.

Not only do many of the things human beings now consume seem unnecessarily harmful, but also the quantities consumed per person often seem outrageous. But since one person's outrage is triggered by the use of something that another values greatly, it is difficult to see how consumption patterns can be changed significantly without substantial social conflict. Much, however, can be accomplished by working hard to increase the energy and material efficiency of the processes by which consumption is served – such as using bikes; mass transit; and light, fuel-efficient automobiles to “consumers” of travel; more efficient production of consumer products; reduction of packaging; etc. – and by conducting marketing and education campaigns to influence consumption patterns toward more efficient, more sustainable ones, with reduced levels of input.

There is sometimes confusion about the relative roles of population and *per capita* consumption in human modification of ecosystems. But one can no more separate their impacts than distinguish the multiplicative roles of a rectangle's length or width in contributing to its area. In the past two centuries, population growth and expanding *per capita* consumption have contributed roughly equally to humanity's assault on its life-support systems. Reducing the assault and transitioning to a sustainable society will require action on both factors. But once it is decided to take action, it will take much longer to humanely reduce population size than to alter human consumption patterns. Given appropriate incentives, the latter can be transformed very rapidly, as World War II mobilizations showed dramatically. Moving toward population reduction now in the USA and globally is required. But if overconsumption by the rich continues to escalate, the benefits of population shrinkage will be compromised. And if underconsumption by the poor is allowed to continue or worsen, the cooperation needed to resolve the human predicament is unlikely to materialize. Equity issues and environmental issues are conjoined twins.

Substitution of Technologies

Of course, it is possible to substitute environmentally benign technologies for environmentally malign ones. For example, with proper education, natural pest control services, enhanced

by integrated pest management, can be substituted in agriculture for broadcast spraying of pesticides. Buildings can be equipped with “more expensive” energy-saving devices that pay for themselves through energy savings within 1–5 years.

Revising Socioeconomic and Political Systems

All of the steps discussed would benefit from public education and broad social discussion of the need to, as the economists say, “get the prices right.” The prices of goods and services need to be adjusted so that they more closely reflect the social costs of each. In other words, externalities should be internalized. The heavy burden put on society due to deterioration of the environment and public health from overuse of large automobiles should be reflected in the prices of both the vehicles and the fuel they consume.

Success at evaluating and implementing the steps that can and should be taken in various nations and diverse economic strata within nations may depend on substantial changes in governmental institutions and the generation of broad social consensus. Substantial revision of socioeconomic and political systems and of human behavior will be required if humanity is to preserve the ecosystem services on which it depends and the biodiversity on which the services themselves depend.

Glossary

Biological control Introduction of a natural enemy (parasite, predator, herbivore, or pathogen) of an undesirable species, usually itself introduced.

Coevolution Evolved mutual adaptations between species, in which each species influences the evolution of the other.

Hybridization Mating between individuals of two different populations, usually classified as separate species. Mixing of their genomes is not required.

Introgression Gene flow between populations whose individuals hybridize, achieved when hybrids backcross to one or both parental populations.

Island biogeography, theory of A theory that the number of species in the biota of each island (or island-like habitat) is in dynamic equilibrium, with species frequently going extinct on the island and new species frequently arriving.

Introduction

What constitutes an impact of an introduced species has never been formally defined. One common use of the term is for interactions with native species (e.g., predation), as well as consequences of these interactions for populations, communities, and structure and function of the ecosystem to which the species was introduced. Frequently this term refers to the economic cost generated by an introduced species (including loss of goods or services and costs of control). A range of less frequent meanings of “impact” will be clear as impacts are described. Nor is the meaning of “introduced species” clearcut. It is widely used for any species introduced to a new region by humans, whether deliberately or accidentally. Some authorities wish to restrict “introduced” to species deliberately imported by humans and describe species that arrive with human assistance but are not deliberately imported as “immigrants.” In this restrictive definition, introduced species plus immigrants comprise the category “nonindigenous species.” A few authors also include as introduced species those that arrive on their own in a location far from their original homes – for example, the Old World cattle egret (*Bubulcus ibis*) in Florida. Finally, an introduced species is often defined legally as one not native to a particular nation; a species carried by humans from one location to another within a nation would not be introduced. Many other common terms – alien, exotic species, bioinvaders – are less precisely used. In this article, introduced species will be those that arrive in a new region with human assistance, deliberately or inadvertently, whether or not the new region is within the national borders of the original range.

The impacts of introduced species are numerous, often subtle, and idiosyncratic. Because intensive study of invasions by introduced species is quite recent, many statements about their impacts are based on intuition rather than empirical data, and intuition is sometimes incorrect. Thus, the decline of the native otter (*Lutra lutra*) in the UK was long attributed to the introduction of the American mink (*Mustela vison*), whereas subsequent research exonerated the mink and

implicated organochlorine pesticides (Chanin and Jefferies, 1978). Conversely, the destruction of the forest birds of Guam was at first attributed to pesticide poisoning before the introduced brown tree snake (*Boiga irregularis*) was proven to be the cause (Perry and Rodda, 2011).

Another complication in predicting and determining impacts of introduced species is that, after introduction, there is frequently a time lag before they spread and begin to exert an impact. For example, Brazilian pepper (*Schinus terebinthifolius*), which now infests ca. 300,000 ha in south Florida, was an innocuous, restricted species for over 50 years (Ewel, 1986). Sometimes the causes of these lags seem evident (e.g., delay in the arrival of an obligatory pollinator for a plant); other times they are mysterious. The opposite phenomenon, dramatic increase in numbers and impact by invaders, followed by a decline independent of directed human actions, is also occasionally observed. For instance, on several Pacific islands massively invaded by the terrestrial giant African snail (*Lissachatina fulica*), a rather abrupt decline in density was observed (Mead, 1961). Similarly, the Pacific alga *Caulerpa taxifolia*, after spreading rapidly for two decades in the Mediterranean, recently began to decline in striking fashion. Again, causes sometimes suggest themselves (e.g., a pathogenic disease), other times they do not.

Despite uncertainties surrounding impacts of introduced species, a recent burst of research shows that they are often dramatic and, in sum, constitute a major, ongoing global change. They are widely recognized as the second greatest cause of species endangerment and extinction (after habitat change, with which they often interact). A recent estimate by D. Pimentel and others suggests an annual global cost of invasive species greater than US\$1.4 trillion (Pimentel *et al.*, 2002). This is not to say that most invaders have dramatic impacts. They do not; most do not even survive. M. Williamson's widely cited tens rule (about 10% of introduced species establish without human assistance, about 10% of those have impacts large enough to be seen as pests) is simplistic, but it accurately depicts the lack of substantial impact by most invaders.

The Geography and Magnitude of Invasion by Introduced Species

How Many Are There, Where Do They Come From, and Where Do They Go?

No comprehensive list of introduced species exists for most taxa in most locations; indeed, there is often no list of native species. However, for well-studied groups, some figures are impressive. In Florida, for example, 27% of established plant species, 8% of insects, 29% of land snails, 24% of freshwater fishes, 22% of reptiles, 5% of birds, and 24% of land mammals are introduced (Simberloff *et al.*, 1997). For the Hawaiian Islands, as for many islands, some of the analogous figures are even greater: almost half the plants, 25% of insects, most freshwater fishes, 40% of birds (Staples and Cowie, 2001). In some areas (e.g., Alaska) there are far fewer introduced species, but almost no regions are immune.

Although the absence of adequate quantitative data makes it difficult to describe this pattern fully, it is widely believed that Eurasian species are more likely to invade other regions than vice-versa and more likely to have large impacts. For instance, most major human pathogens and most plant pathogens that have had global impacts originated in Eurasia. Similarly, more Eurasian insects, vertebrates, and plants have invaded other regions than *vice-versa*. The reasons for this imbalance are obscure. Some authors have argued that Eurasian species have an innate superiority, generated either by the larger numbers of species evolving greater competitive ability on the larger landmass, or by the happenstance that Eurasian species were highly coevolved – plants, pathogens, and animals (including especially grazers and humans) – and overwhelmed native species by their joint action. For example, the structure and behavior of Eurasian hooved livestock was devastating to native tussock grasses in the North American prairie but favorable for Eurasian turfgrasses, which now dominate vast regions (Mack, 1986).

However, even if Eurasian species, singly or in groups, were not innately superior, one might have expected a preponderance of them among introductions, because the opportunities for such species to reach other regions were greater throughout most of recent history. For instance, the majority of introduced insects in the US through the eighteenth century came from Europe in soil ballast, loaded in Europe and exchanged in North America for various raw materials (Lindroth, 1957). Similarly, as Europeans colonized other regions, they formed acclimatization societies to introduce the birds of their homelands (Lever, 1992). Except for gamebirds, there was little analogous movement of species in the opposite direction. Nowadays, as travel and trade are burgeoning worldwide, opportunities for introduction from any region to any other one are greatly enhanced, and one might expect habitat and climatic matching to become more important as limiting factors.

When Did They Get There?

The timing of introductions has depended heavily on available means of transport and patterns of travel and trade, and it has tended to increase strongly from the late eighteenth century through the present. For example, introductions of aquatic

plants and animals into the Great Lakes rose steadily from one species between 1810 and 1839 to over 40 between 1960 and 1990, a surge associated with the opening of the Saint Lawrence Seaway (Mills *et al.*, 1993). The advent of rapid steamship transport across oceans coincided with a dramatic increase in introductions of many taxa, as hitchhikers that could not have stayed alive over a month or more in transit were able to survive a voyage of two weeks across the Atlantic, for example. Air travel decreased the need to survive a long transit period still further. Overlaying this dominant pattern of increasing rates of introduction with increased transport volume and decreased transit time are idiosyncrasies associated with particular taxa and regions. For example, beginning around 1920, there was a decrease in the rate at which foreign insect species, especially herbivorous species, were introduced to the US; this downturn coincided with the enforcement of plant quarantine laws. At the same time, a dramatic increase of introduction of wasp species reflected greatly increased biological control efforts, especially the use of parasitic wasps (Simberloff, 1986).

Distribution of Introduced Species among Habitats

Habitats modified or routinely disturbed by humans generally house more introduced species and larger populations of introduced species than do pristine habitats, though even the latter are occasionally invaded. The reason for this pattern has been hotly debated. In general, the very fact of human disturbance renders a habitat less suitable to the native species that had evolved in the original habitat. However, some species, often associated with humans, are superbly adapted to habitats that humans create. Thus, certain introduced plants are routinely found on lists of serious weeds from many parts of the world. A common claim that disturbed habitats are invisable because they are species-poor is incorrect. Many habitats relatively undisturbed by humans, such as salt-marshes and mountaintops, have few native species, but they also have few introduced species, and for the same reason – they are biologically difficult environments and few species of any kind have physiological adaptations that permit them to thrive there. Conversely, enormously diverse tropical communities often have as many invaders (with as large impacts) as less species-rich temperate analogs. Nor does periodic disturbance per se automatically conduce to invasiveness. For example, the intact upland pine forests of north Florida are far less stricken by invaders than many other habitats in the state, yet they frequently burn naturally because of lightning strikes. If anything, this disturbance favors the many native species that are adapted to a fire regime over a plethora of potential invaders that are not. However, the increasing invasion of this region by fire-adapted cogon grass (*Imperata cylindrica*) poses a threat to the entire forest ecosystem (Schmitz *et al.*, 1997).

Most well known examples of introduced species with enormous impacts come from either terrestrial or freshwater habitats. Marine habitats are less represented in the invasion literature. Freshwater habitats – lakes and rivers – can often be seen as habitat islands, surrounded by land, and thus their communities are believed to be inherently invisable for the same reasons that islands appear to be particularly invisable,

as will be discussed in the following section. Certainly, many lake and river communities have evolved without certain types of organisms, such as large predatory or herbivorous fishes, so their species are particularly prone to damage from introduced species of these particular sorts. Whether marine habitats have suffered less impact from introduced species is highly questionable. Terrestrial habitats are immediately visible, so the effects of introduced species are surely more likely to be detected there than in the sea, just as the general ecology of most marine habitats is poorly studied and understood relative to that of most terrestrial habitats. Additionally, it is now widely recognized that many marine species that had been viewed as native over wide regions are in fact of unknown provenance – they are “cryptogenic.” In most places they may well have been accidentally introduced by humans. Finally, a number of marine invasions have been observed lately that vie in apparent impact with the most heralded terrestrial and freshwater invasions. The tropical alga *Caulerpa taxifolia*, purged from the public aquarium in Monaco in the early 1980s, spread to cover over 10,000 ha of nearshore habitats off the coasts of Spain, France, Italy, Monaco, and Croatia. It particularly overgrew and replaced meadows of marine grasses such as *Posidonia oceanica*, the nursery and home of many fishes and invertebrates (Meinesz, 2001). As noted previously, populations of *C. taxifolia* have recently begun to recede, but the related Pacific alga *C. racemosa*, which arrived in the Mediterranean later, has spread widely. In the Black Sea, the western Atlantic ctenophore *Mnemiopsis leidyi* was first recorded in 1982. By 1988, its biomass exceeded that of all other zooplankton combined, and, as this comb jelly is a predator, its impact on other animals, including young fishes, was enormous. It caused a dramatic crash of several commercial fisheries. About a decade later, another comb jelly from the western Atlantic, *Beroe ovata*, arrived in ballast water, preyed on and greatly reduced populations of *M. leidyi*, and the Black Sea ecosystem began to recover (Shiganova, 2011).

Island Vulnerability

Islands are notoriously prone to ecological damage by introduced species. Many island bird species and subspecies have been eliminated by introduced rats, feral cats, and other introduced carnivores. In the West Indies, the small Indian mongoose (*Herpestes auropunctatus*) has extinguished several species and subspecies of endemic snakes and lizards (Hays, 2011). Introduced grazers have caused many plant extinctions on islands. The introduced carnivorous rosy wolf snail, *Euglandina rosea*, has eliminated at least seven species of terrestrial snails on the Pacific island of Moorea alone, as well as many populations of endemic tree snails in the Hawaiian Islands (Cowie, 2001). Worldwide, about 1.6 times as many mammal species and three times as many bird species have been successfully introduced to islands as to mainland areas (Groombridge, 1992).

The reasons for the great number of introduced species on many islands, and their apparently great impacts on many of them, are probably threefold. First, there are generally more deliberate attempts to introduce species to islands. As mainland inhabitants colonized islands, they saw them as biotically

impoverished and attempted to introduce species – often those from home – to fill the perceived gap. Second, many of the islands that have been most assaulted by introduced species were massively modified largely independently of introductions. For example, almost all the lowland areas of the Hawaiian Islands, Mascarenes, and many of the West Indies were cleared of native species for agricultural and housing purposes. That the introduced species largely replaced them does not necessarily mean that the native species were in some sense weaker than the invaders; rather, the habitats to which the native species were adapted were simply removed. Because of the smaller size of islands than mainland, habitat destruction on islands was generally much less likely to leave refugia in which the native species persisted. Third, the biotae of oceanic islands often evolved without entire groups of organisms, and so lacked adaptations to survive their impacts once they were introduced. Thus, most oceanic islands lack native predatory mammals, so birds evolved to nest on the ground and were highly susceptible to the invasion of such species. Similarly, native browsing and grazing herbivorous mammals are lacking from islands, so the native plants have not evolved traits to survive herbivory when mammals such as goats and reindeer are introduced.

Direct Effects

Habitat Modification

The most widespread impacts of invaders are usually due to modification of the habitat, which affects many species together. Almost all introduced species believed to have had major impacts on entire ecosystems or landscapes have done so by modifying habitats.

Grazing and Rooting

Goats were introduced to St Helena in 1513 and built up enormous herds. These are believed to have extinguished at least half of some 100 endemic plant species before botanists had even visited the island (Cronk, 1989). On the island of South Georgia, grazing by introduced reindeer (*Rangifer tarandus*) has heavily degraded tussock grassland, mesic meadow, dwarf-shrub sward, and dry meadow communities (Leader-Williams, 1988). These changes have facilitated erosion and invasion by exotic plants. In many places, these changes resulted in a totally new plant community. Recovery of certain plant communities, and the insects that inhabit them, may take a long time, but enclosure experiments show that few of the changes are irreversible. European wild boar (*Sus scrofa*), feral domestic hogs, and hybrids between them have wreaked havoc in both bottomland and upland forests in the US. For example, in the Great Smoky Mountains National Park, they “root” primarily in high-elevation deciduous forests in the summer, reducing understory cover and number of species. By selective feeding, they can locally extinguish plant species with starchy bulbs, tubers, and rhizomes. They greatly modify soil characteristics by thinning the forest litter, mixing organic and mineral layers, and accelerating mineral leaching (Singer *et al.*, 1984).

Shading and Overgrowth

South American water hyacinth (*Eichhornia crassipes*) blankets many nearshore areas of Lake Victoria, some lakes and rivers of the US Southeast, and many water bodies in other regions. It blocks light and smothers beds of native submersed vegetation. Decaying water hyacinth can deposit over 1000 metric tons (wet weight) of detritus per hectare per year, which in turn can heavily modify water chemistry, such as nutrient concentrations. Dissolved oxygen drops, affecting many animals. The entire biotic community changes (Hill *et al.*, 2011). Terrestrial plants such as Asian kudzu (*Pueraria montana*) in the southeastern US can similarly cover existing vegetation and eliminate it by shading, as can marine plants such as the tropical algae *Caulerpa taxifolia* and *C. racemosa* in the Mediterranean.

Modified Fire Regime

In much of the American West and Hawaii, Old World grasses such as cheatgrass (*Bromus tectorum*) increase the frequency and intensity of fires, greatly harming native plants and the animals that use them (Mack, 2011). Similarly, the Australian paperbark tree (*Melaleuca quinquenervia*) has a spongy outer bark and highly flammable foliage, and it also produces a more abundant litter than native herbaceous communities in south Florida. These features have produced a changed fire regime that has facilitated the invasion of 100,000 ha. Both tree and ground fires are now more intense and frequent, to the detriment of the native plants (Serbesoff-King, 2003). An added threat to the region is the recent arrival in the area of Old World climbing fern (*Lygodium microphyllum*), which transmits fires to the top of the tree canopy (Volin, 2004).

Modified Hydrology

Mediterranean salt cedars (*Tamarix* spp.) have invaded the US Southwest. They are deeply rooted and transpire rapidly; once established, they can survive on water deep in the soil, and their transpiration is a significant pathway of water loss in arid areas. For example, at Eagle Borax Spring in Death Valley, California, within 25 years of invasion by salt cedar, the surface water of what had been a large marsh had disappeared completely, along with the majority of its associated biota (McDaniel *et al.*, 2005). In Israel, Australian *Eucalyptus* trees have been used deliberately to drain swamps and bogs, thus eliminating the original vegetation and animals dependent on them (Biger and Liphshitz, 1995). In addition to changed evapotranspiration rates, plants can also affect hydrological regimes by changing soil elevation. Off the southern coast of Great Britain and parts of the coast of the state of Washington in the US, the cordgrass *Spartina anglica* has elevated intertidal areas and transformed gently sloping, productive mudflats into poorly drained marshes with enormous impact on resident animal species. *Spartina anglica* is a species formed in Great Britain in the late nineteenth century by the hybridization of introduced North American cordgrass (*S. alterniflora*) with native European *S. maritima* (Simberloff, 2011).

Modified Nutrient Regime

Many plant invaders fix nitrogen, and, in nitrogen-poor areas, this added increment can favor other invaders and be detrimental to native species, which have evolved to thrive in a

low-nitrogen environment. The Atlantic nitrogen-fixing shrub *Morella faya* has invaded young, nitrogen-deficient volcanic regions of Hawaii. There are no native nitrogen-fixers, and the invader thus alters productivity, nutrient cycling, and ecological succession. Because many nonindigenous plant species in Hawaii are more successful on more fertile sites, *M. faya* may enhance the likelihood of other invasions (Vitousek, 1986).

Competition

Some introduced species use a particular resource so effectively that they deprive native species of it. In addition, an introduced species can depress a native one not by eliminating some resource but by direct interference.

Resource Competition

Shading and water depletion, already discussed, are means by which some introduced plants outcompete native species for a crucial resource. Introduced animals have similar effects. For instance, the house gecko, *Hemidactylus frenatus*, has invaded many Pacific islands, and it depresses the insect food base locally so that some native lizard populations decline (Petren and Case, 1998). In Great Britain, the greater foraging efficiency of the introduced American gray squirrel (*Sciurus carolinensis*) has led to the decline of the native red squirrel (*S. vulgaris*). The impact of the invader is enhanced by the fact that it carries a pathogen to which it is resistant but that devastates the native squirrel (Gurnell *et al.*, 2004).

Interference Competition

The South American fire ant, *Solenopsis invicta*, which has spread throughout much of the southeastern US, attacks individuals of many native ant species and is replacing some species, such as the "native" fire ants (perhaps themselves pre-Columbian introductions) *S. geminata* and *S. xyloni* in several habitats (Sanders, 2011). In a plant analog of aggression, the African crystalline ice plant, *Mesembryanthemum crystallinum*, accumulates salt (Vivrette and Muller, 1977), and the salt remains in the soil when the plant decomposes. In California, this ice plant excludes native plants that cannot tolerate the salt (Vivrette and Muller, 1977). In both of these examples, the invader does not actually render a resource in short supply for native species; rather, it directly inhibits the native, preventing its access to the resource.

Predation

Some predaceous invaders have devastated particular native species or groups of them. The Nile perch (*Lates nilotica*), introduced to Lake Victoria, eliminated many species of endemic cichlid fishes by eating them (Pringle, 2011). Introduced rats (*Rattus* spp.) on over 80% of the world's archipelagoes have destroyed at least 37 species and subspecies of island birds worldwide (Pascal, 2011). The brown tree snake and the rosy wolf snail, mentioned previously, are predators that have extinguished many native prey species. These are all dramatic examples of how an introduced predator can affect a native fauna that has not coevolved with it. However, even prosaic

introduced predators may have a substantial impact on native prey. For instance, there are up to 30 million feral housecats in the US, and in Wisconsin plus Virginia alone they are believed to kill more than six million birds annually (Winter, 1999).

Many predators have been introduced deliberately for biological control of previously introduced species, especially when the latter inflict losses on agriculture. The introduction in 1889 of the Australian vedalia beetle (*Rodolia cardinalis*), which controlled cottony-cushion scale (*Icerya purchasi*) on California citrus, is an early example, and there are many other successes (Simberloff, 2012). More recently, biological control has been employed for conservation purposes. On the island of St Helena, a tropical American scale insect (*Orthezia insignis*) that had threatened the native gumwood tree (*Commidendrum robustum*) was controlled by introducing a South American lady beetle, *Hyperaspis pantherina* (Booth *et al.*, 2001). However, some predators introduced for biological control have devastated nontarget native species while exerting little if any control on populations of the target. The rosy wolf snail (*Euglandina rosea*) discussed previously is a prime example; it was introduced to many islands to control the giant African snail but failed to do so because the latter snail is too large. Similarly, the small Indian mongoose, previously mentioned as having extinguished native reptiles in the West Indies, was introduced there and on the Hawaiian Islands, Fiji, Mauritius, Okinawa, and other islands for the biological control of rats. On all these islands, it preyed on native, nontarget species, sometimes to the point of endangerment or extinction. The mosquitofish (*Gambusia affinis*) from Mexico and Central America, introduced in Europe, Asia, Africa, Australia, and many islands for mosquito control, is widely seen in many regions as being at best no better than native predators at controlling mosquitoes. It often preys on other small fishes as well as invertebrates, some of which prey on mosquito larvae. For instance, in Australia, it is implicated in the extinction of several endemic fish species through predation and both interference and resource competition (Pyke, 2008).

Herbivory

The extinction of half of the native flora of St Helena by goats, discussed earlier, shows that herbivory by introduced species on native ones can have major impacts. Other examples abound in a variety of habitats. Chinese grass carp (*Ctenopharyngodon idella*) have been introduced to Europe, Africa, and North America to control aquatic plants. Although the targeted plants are generally introduced species, the grass carp is not highly selective and often prefers native plants. It is so voracious that it can completely eradicate nontarget species from particular water bodies before foraging on the target species (Bain, 1993). Herbivory by introduced European rabbits (*Oryctolagus cuniculus*) has caused enormous damage on islands worldwide. Their impact in Australia is legendary. The most serious damage there is by the stripping and killing of seedling trees and perennial shrubs. In addition, rabbits often cause extensive erosion (Thompson and King, 1994).

Innumerable crop plants, most of them introduced, have been devastated by introduced insects. Damage in the US from

the Russian wheat aphid (*Diuraphis noxia*) alone exceeded \$600 million between 1987 and 1989 (US Congress Office of Technology Assessment, 1993). The South American cassava mealybug (*Phenacoccus manihoti*) has invaded most cassava-growing regions of Africa and causes yield losses of up to 84% (Norgaard, 1988). Similarly, introduced insects attack both native and introduced trees, often with staggering impact. Losses in eastern US forests to the European gypsy moth (*Lymantria dispar*) were estimated at \$764 million in one year alone (US Congress Office of Technology Assessment, 1993). The Asian balsam woolly adelgid (*Adelges piceae*) has eliminated the Fraser fir (*Abies fraseri*) in many areas of the southern Appalachians, while the Asian hemlock woolly adelgid (*A. tsugae*) is currently devastating hemlock (*Tsuga*) forests through the eastern US, and the Asian emerald ash borer (*Agrilus planipennis*) threatens to eliminate extensive forests of ash (*Fraxinus*) in the US East and Midwest (Simberloff, 2012).

Herbivorous insects have been employed in biological control projects against many introduced aquatic and terrestrial weeds. Among striking successes are the use of the South American cactus moth, *Cactoblastis cactorum*, against pest prickly pear (*Opuntia* spp.) in Australia and the South American alligatorweed flea beetle (*Agasicles hygrophila*) on aquatic alligatorweed (*Alternanthera philoxeroides*) in Florida. In each instance, the weed had covered vast areas before the insect introduction, which subsequently limited it to small, ephemeral infestations (Simberloff, 2012). Such introductions of insects for control of introduced weeds have occasionally led to threats to nontarget native species. For example, the cactus moth, introduced to control pest prickly pear on the island of Nevis in the West Indies, reached the Florida Keys, where it attacked every individual of the native semaphore cactus, *Opuntia coricolla*, and it has now spread north from Florida to South Carolina and west to Louisiana; it is believed to threaten 79 species of *Opuntia* in the US and Mexico (Simberloff, 2012). The Eurasian weevil *Rhinocyllus conicus*, introduced to North America to control Eurasian pest thistles, especially musk thistle (*Carduus nutans*), attacks several native thistles, including the endangered Suisun thistle (*Cirsium hydrophilum* var. *hydrophilum*) (Simberloff, 2012). The key to these unplanned threats to native species, in each instance, is that the introduced insect feeds on several species in addition to the target pest plant and is able to maintain high numbers on alternative hosts (generally the target species), so that decline of the native species did not induce a decline in populations of the herbivore.

Parasitism and Disease

Introduced pathogens of various sorts have had enormous impacts. The most damaging to entire ecosystems are plant pathogens that affect dominant native plants; in so doing, they affect entire communities that interact with these plants. The Asian chestnut blight fungus (*Cryphonectria parasitica*) reached New York City in nursery stock in the late nineteenth century. In less than 50 years, it spread over about 100 million hectares of the eastern US, destroying the aerial parts of almost all mature chestnut (*Castanea dentata*) trees. As chestnut had

been the most common tree in many forests, the ecosystem impacts of this invasion were almost certainly enormous, although few crucial data were gathered. Several insect species host-specific on chestnut went extinct, and nutrient cycling rates were probably greatly modified (Freinkel, 2007).

A pathogen of animals that affected many entire ecosystems was the virus rinderpest, native to India. Introduced to sub-Saharan Africa in cattle in the 1890s, it infected many native ungulate species, with mortality in species such as the wildebeest (*Connochaetes* spp.) and buffalo (*Syncerus caffer*) surpassing 90%; the distribution of some species remains affected a century later. When ungulate populations plummeted, populations of carnivores such as the lion (*Panthera leo*) crashed as well. Because of the crucial role played by ungulates in aspects of vegetation structure and dynamics, the impact of rinderpest far surpassed the death of individuals it infected (Plowright, 1982). A long campaign to rid Africa from rinderpest finally succeeded in 2011 (McNeil Jr, 2011), but it is uncertain how long it will take for native ecosystems to recover, if they ever do.

Many introduced diseases have heavily affected individual species or small groups of them without apparent major impact on entire ecosystems. Ranges of Hawaiian native birds have been drastically circumscribed by habitat destruction, but avian malaria, caused by *Plasmodium relictum capistranoae* and vectored by introduced mosquitoes, afflicts the remaining populations and helps restrict them to upper elevations. The plasmodium was introduced with Asian songbirds (van Riper *et al.*, 1986). The European fish parasite *Myxosoma cerebralis* causes whirling disease in salmonid fishes. Following World War II, live North American rainbow trout (*Oncorhynchus mykiss*) were transferred freely among European sites. There they acquired the parasite from the native brown trout, *S. trutta*, which has significant resistance. Eventually, frozen European rainbow trout were widely exported. The parasite probably reached North America in imported frozen fishes. Either these were fed accidentally to fish in a trout hatchery in Pennsylvania, or the viscera may have been discarded in streams near the hatchery. In any event, hatchery fishes became infected, and these were shipped to many other states. In large parts of Montana and Colorado, the great majority of rainbow trout contract the disease, and sport fisheries have collapsed in both states (Bartholomew and Reno, 2002).

Introduced macroparasites also often have major impacts. The parasitic plant witchweed (*Striga asiatica*) probably invaded North Carolina from Africa with military equipment after World War II. It attacks primarily grasses, including corn, and is a sufficient agricultural pest that it has been the target of a long eradication campaign and associated quarantine, which have led over 50 years to a great reduction in its introduced range (Eplee, 2001). The trematode *Cyathocotyle bushiensis*, which causes heavy mortality in ducks, has advanced along the St Lawrence River recently concurrently with its invasive introduced intermediate host, the Eurasian faucet snail *Bithynia tentaculata* (Sauer *et al.*, 2007).

Many parasitic wasps and flies, as well as some disease pathogens, have been introduced as biological control agents for introduced pests. For example, the yellow clover aphid (*Therioaphis trifolii*) is controlled in California by three parasitic wasps, *Praon palitans*, *Trioxys utilis*, and *Aphelinus semiflavus*

(van den Bosch *et al.*, 1964). Populations of the cassava mealybug in Africa, discussed earlier, have been greatly reduced by the introduced South American parasitic wasp *Epidinocarsis lopezi*. Perhaps the best known biological control pathogen is the New World myxoma virus, introduced to mainland Europe (where the European rabbit is native) and Great Britain and Australia (where it is introduced). Initial epizootics caused over 99% mortality in Great Britain and Australia, and over 90% in France. The initial virulent strains in all three countries largely evolved to more benign strains, and, at least in Great Britain and Australia, rabbits evolved a degree of resistance. Thus, successive epizootics caused decreasing mortality, until an equilibrium appeared to have been reached (Bartrip, 2008). More recently, rabbit calicivirus from Asia was introduced to Australia and New Zealand, again initiating epizootics that will almost certainly attenuate in time as the virus becomes more benign and rabbits more resistant. A number of pathogenic fungi have been introduced to control weeds, with varying degrees of success. For instance, African bridal creeper (*Asparagus asparagoides*) has been substantially controlled in parts of Australia by the African rust fungus *Puccinia myrsiphylli* (Morin and Edwards, 2006).

Hybridization and Introgression

Introduced species can eliminate native species by mating with them, a particularly strong threat when the native species is not as numerous as the introduced one. Both the New Zealand grey duck (*Anas superciliosa superciliosa*) and the Hawaiian duck (*A. wyvilliana*) are thus threatened by extensive hybridization and introgression with the North American mallard, (*A. platyrhynchos*), introduced as a game bird (Rhymer and Simberloff, 1996). Similarly, the white-headed duck (*Oxyura leucocephala*), now restricted in Europe to Spain, is threatened there by hybridization and introgression with North American ruddy ducks (*O. jamaicensis*), which were introduced to Great Britain as an amenity, escaped, and eventually reached Spain (Muñoz-Fuentes *et al.*, 2007).

Both plants and animals are threatened by such introgression, and its extent is increasingly demonstrated by molecular techniques. This problem is much more common in regions that exchange closely related species, such as Europe and North America, than in those with species so distantly related that they are unlikely to be able to mate and exchange genes, such as Australia and either Europe or North America. Exchange of genes is not even necessary for hybridization with an introduced species to affect a native species inimically. Many females of the endangered European mink (*Mustela lutreola*) hybridize with male introduced American mink (*M. vison*), which become sexually mature earlier than the male European mink. The embryos are all aborted, but the loss of reproduction by the European mink exacerbates their population decline (Maran and Henttonen, 1995).

Indirect Effects

The foregoing impacts of introduced species are direct effects of various sorts. The actions of individuals of the introduced

species are directly on individuals (and often, ultimately, on populations) of one or more native species; they may attack them, eat them, poison them, infect them, and so forth. However, an introduced species can also affect other species indirectly in many ways.

Classical Indirect Effects

A strictly defined indirect effect occurs when one species affects the interaction between two others. For example, the chestnut blight led to the replacement of chestnut in much of the eastern US by oak species. Red oak (*Quercus rubra*) increased greatly, and this species is particularly susceptible to oak wilt disease (*Ceratocystis fagacearum*). The increase in oak wilt disease on red oak, in turn, raised the frequency of oak wilt disease on many less susceptible native oak species. Thus, the chestnut blight fungus indirectly affected the interaction of oaks and oak wilt disease, in addition to its direct effect on chestnut (Ellison *et al.*, 2005).

A common sort of indirect effect, called “apparent competition,” occurs when the population of an introduced species becomes so large that it sustains a large population of a predator, parasite, or herbivore. If the predator or parasite does not greatly affect that population of the introduced species, it may nonetheless attack some native species and cause its population to decline. The introduced species is not actually competing with the native species, but the impact “appears” to be the same. A case in point is the Eurasian weevil *Rhinocyllus conicus*, discussed previously, which was introduced to North America to control invasive Eurasian musk thistle (*Carduus nutans*). Enough musk thistle remains that weevils remain numerous, and they attack several native North American thistle species, bringing one (the Suisun thistle, *Cirsium hydrophilum* var. *hydrophilum*) to the brink of extinction. Another common indirect effect is the “trophic cascade,” in which an introduced species in a higher trophic level, by feeding on a species in the trophic level just below it, reduces the population of the latter sufficiently that the population of species in a still lower trophic level, previously controlled by the latter, increases. A major trophic cascade was precipitated by the introduction of the sea lamprey (*Petromyzon marinus*) to the North American Great Lakes in the nineteenth century. Lampreys devastated populations of all large native fishes in the lakes, and the declines of the latter rippled through the food web, causing increases in populations of several smaller fish species (Sorensen and Bergstedt, 2011). Successful biological control of plant-eating insects relies on trophic cascades. For instance, the introduced lady beetle that rescued the St Helena gumwood tree, discussed earlier, did so by eating the scale insect that was eating gumwood leaves.

Classical indirect effects can be complex and surprising. For example, two gall flies (*Urophora affinis* and *U. quadrifasciata*) introduced to control spotted knapweed (*Centaurea maculosa*) in western North America failed to do so. However, they have established enormous populations and have generated a substantial indirect effect by subsidized populations of the deer mouse *Peromyscus maniculatus*, comprising 85% of deer mouse winter diet in knapweed-infected areas and elevating deer mouse populations two to threefold. The full impact of

increased populations of deer mice, a generalist feeder, are unknown but could include eating seeds of native plants, competition with other small mammals, predation on and competition with insects, and even increased transmission of the hantavirus to humans (Pearson and Callaway, 2003).

Chain Reactions

A number of the introductions discussed earlier affected one species directly, but this direct effect generated subsequent impacts in chain-like fashion. Thus, the direct effect of chestnut blight on American chestnut led indirectly to the extinction of several insect species host-specific on chestnut. The modification of nutrient cycles as a chestnut-dominated litter was replaced by litter dominated by leaves of oaks and other species almost certainly affected populations of litter inhabitants as well as plants, but these effects were never investigated. Rabbits in Australia directly affected certain plant species, as noted earlier, and also probably directly contributed to the elimination of two small burrowing marsupials, the boodie rat (*Bettongia lesueur*) and the lesser bilby (*Macrotis leucura*) by competition for burrows. Furthermore, rabbits indirectly led to the elimination of the common wombat (*Vombatus ursinus*) from part of its range by modifying succession and locally eliminating native perennial plants. On coastal islands, the erosion and vegetation changes caused by rabbits have been highly detrimental to seabirds that use these islands for resting and breeding.

Some chain reactions induced by introduced species are so complicated that predicting them would have been difficult. Caterpillars of the large blue butterfly (*Maculina arion*) in Great Britain required development in underground nests of the ant *Myrmica sabuleti*. The ant cannot nest in overgrown areas. Changing land use patterns and reduced livestock grazing had left introduced rabbits as the main grazer maintaining the habitat. The biological control introduction of myxoma virus, discussed previously, reduced rabbit populations sufficiently that ant populations declined, and the butterfly was extirpated (Ratcliffe, 1979).

Chain reactions can generate effects far from the site of the initial introduction. For example, landlocked kokanee salmon (*Oncorhynchus nerka*) were introduced to Flathead Lake, in western Montana, in 1916 and largely replaced native cutthroat trout (*O. clarki*) as the dominant sportfish. By 1931, the kokanee were spawning in McDonald Creek (Glacier National Park), some 100 km upstream from Flathead Lake, and the spawning population was so large that it soon attracted large populations of bald eagles, grizzly bears, and many other predators. The catch of kokanee rose to over 100,000 fishes per year through 1985. Between 1968 and 1975, the opossum shrimp (*Mysis relicta*), native to several large deep lakes in North America and Sweden, was introduced to three lakes in the upper portion of the Flathead catchment in a misguided attempt to enhance kokanee productivity. The shrimp drifted downstream, reaching Flathead Lake by 1981. There was an immediate, dramatic decline in densities of copepods and especially cladocerans preyed on by the shrimp. This competition with the shrimp for prey caused the kokanee population to decline rapidly; there was no catch at all in 1988 and

1989. Bald eagle numbers fell precipitously, as did those of grizzly bears and several other predators (Spencer *et al.*, 1991).

Vectoring of Pathogens

In a number of instances discussed earlier, an introduced species carried a pathogen that greatly affected one or more native species – rinderpest, whirling disease, avian malaria. In some cases, these could be classified as classical indirect effects. For instance, in Hawaii the avian malaria plasmodium changed the interaction between introduced mosquitoes and native forest birds, to the detriment of the latter. The impact of an introduced pathogen can be more complex – for example, the introduced species that carries it to a new region need never be found together with a native species ultimately affected. Consider the introduction of the Chinese grass carp to the US. The carp was introduced to Arkansas in 1968; it spread to the Mississippi River, carrying with it a parasitic tapeworm from Asia, *Bothriocephalus acheilognathi*. The tapeworm quickly infested other fishes, including the red shiner (*Notropis lutrensis*), a popular bait fish. Fishermen or bait dealers introduced infected red shiners to the Colorado River, and by 1984 they had reached the Virgin River, a Utah tributary. There they infected the woundfin (*Plagopterus argentissimus*), a native minnow already threatened by dams and water diversions. Tapeworm infections caused woundfin numbers to decline precipitously, possibly because they are less able to compete with the red shiner, which have some resistance to the tapeworm (Moyle, 1993).

Invasional Meltdown

Some ecological theories suggest that introduced species should interfere with one another and thereby lessen one another's impact. The theory of island biogeography, for example, implies that each successive species in a series introduced to an island (or a habitat island) has a lower probability of surviving. Biological control practitioners have argued about whether releasing several species of potential natural enemies of a single pest might lessen the overall impact on that pest because of competition among them. However, positive interactions between introduced species are often detected. Sometimes one introduced species facilitates the existence and enhances the impact of another; other times the combined impacts of two or more introduced species exceed the sum of what the same species might have accomplished individually. Such situations, in which different introduced species enhance one another's impacts, are collectively termed "invasional meltdown." The existence of many such cases suggests that an accelerating wave of invasions with ever-increasing impacts may characterize the future in many regions (Simberloff and Von Holle, 1999).

Introduced Animals Pollinating and Dispersing Introduced Plants

Introduced fig (*Ficus*) species are frequently planted as ornamentals in south Florida. If the wasp species that pollinates a fig species in its native range is absent, the fig cannot

reproduce. Thus, figs in Florida long remained where planted. However, within the past 25 years, breeding populations of three host-specific pollinating wasps were introduced to Florida, and the species they pollinate now regularly produce seeds. *Ficus microcarpa* is spreading most quickly and has become an invasive weed, the small fruits of which are dispersed by birds and ants. The spread of the same complex of *F. microcarpa* trees and its wasp pollinator *Parapristina verticillata* is also occurring in Bermuda, Mexico, and Central America.

Some introduced animals disperse introduced plants that disrupt native plant communities. The red-whiskered bulbul (*Pycnonotus jocosus*) has dispersed a number of alien species, such as *Rubus alceifolius*, *Cordia interrupta*, and *Ligustrum robustum* on the Indian Ocean island of La Réunion. *Cordia* was not viewed as a problem until it was widely distributed by the bulbul; the bird is the primary dispersal agent for *Ligustrum*. In the Hawaiian Islands, introduced pigs selectively eat and thus disperse several invasive introduced plant species, and their rooting and defecation favor several introduced invertebrates. Further, the pigs grow larger because of the presence of introduced, protein-rich European earthworms in the soil. The Asian myna bird (*Acridotheres tristis*), introduced to control pasture insects, has dispersed the New World weed *Lantana camara* widely in the lowlands of the Hawaiian islands, including into native forest areas.

Introduced Plants that Modify Habitat

As noted in a previous section, the Atlantic nitrogen-fixing shrub *Morella faya* in Hawaii may facilitate invasion by other introduced plants that are currently limited by the nitrogen-poor volcanic soil and absence of native nitrogen-fixers. This plant also enhances populations of introduced earthworms, which in turn increase the rate of nitrogen burial and thus exacerbate the impact of the plant on nitrogen cycling. The soil drying by introduced salt cedars already described favors the introduction of non-native grasses in both the US Southwest and Australia. The increased soil salinity produced by the African crystalline ice plant, described earlier, does more than kill native plants. When wind or other disturbances create holes in the carpet of ice plant, they are colonized not by native plants but by the ice plant itself or by weedy introduced plants such as *Malva parviflora* or *Erodium cicutarium*.

Many invasive introduced plants increase fire frequency or intensity to the detriment of native species but to their own advantage and that of other invaders. Old World grasses have come to dominate many New World grasslands through this facilitation. For instance, in Hawaii introduced perennial tufted beardgrass, *Schizachyrium condensatum*, invaded seasonal submontane shrub-dominated woodland. It fostered much more frequent fires over larger areas, killing most native trees and shrubs. But *S. condensatum* recovered quickly and the even more flammable introduced perennial molasses grass, *Melinis minutiflora*, also invaded (D'Antonio and Vitousek, 1992).

Introduced Animals that Modify Habitat

The disturbance wrought by large, congregating, introduced herbivores in North America favored the establishment of

Eurasian grasses adapted to such animals and helped them to replace native tussock grasses. Similarly, the Asian water buffalo (*Bubalus bubalis*), introduced to northeastern Australia as a beast of burden and for meat, spread throughout the flood plain of the Adelaide River by the late nineteenth century. It devastated native plant communities, compacted the soil, eroded creek banks, and altered hydrology. A Central American shrub, *Mimosa pigra*, had been a minor, noninvasive weed in the vicinity of Darwin for a century. This legume produces large numbers of small seeds that are readily dispersed by water. The sundering of the flood plains by the water buffalo created ideal germination habitat for *M. pigra* seedlings. In many areas, native sedgelands were converted to a monoculture of *M. pigra*.

The Caspian zebra mussel, *Dreissena polymorpha*, arrived in the Great Lakes in the 1980s. Its huge numbers and great filtering ability have greatly affected native freshwater communities over much of the eastern and midwestern US. In particular, they convert large amounts of seston into excreted feces, creating a soft substrate of rich organic material. Among species whose populations are increased by the zebra mussel is the invasive Eurasian faucet snail discussed previously. The filtering also increases water clarity, and this change has favored certain invasive macrophytes, such as Eurasian watermilfoil (*Myriophyllum spicatum*).

Mutualisms

A number of instances in which one introduced species facilitates the existence, spread, and population growth of another introduced species constitute mutualisms, in that the latter species also aids the former. For example, introduced macrophytes like Eurasian watermilfoil provide additional settling substrate for the zebra mussel, and they can also help the mussel disperse between water bodies. *Mimosa pigra* aided water buffalo by protecting them from aerial hunters trying to eradicate them. Fig wasps and their associated fig species obviously form coevolved mutualistic introduced species pairs. In the Hawaiian islands, introduced African big-headed ants (*Pheidole megacephala*) tend an introduced scale insect, *Coccus viridis*, a classic mutualism. The scale is on the introduced plant *Pluchea indica*; among other impacts, the ant hinders introduced predatory lady beetles and parasitic wasps. In this one case, a range of interactions are taking place among an entire assemblage of introduced species. Sometimes, as with *Mimosa pigra* and water buffalo, the mutualists cannot have coevolved, as they originate on different continents. The African big-headed ant in Hawaii also tends the South American gray pineapple mealybug (*Dysmicoccus neobrevipes*), a particular pest because it helps spread a wilt disease of pineapple.

Time Lags and Evolution

Impacts of introduced species may change dramatically, as, for example, when an invader is quiescent during a time lag, after which it rather abruptly spreads and increases in number. As observed in the Introduction section, such time lags complicate efforts to predict the impacts of an introduced species and

are sometimes mysterious. It is frequently suggested that a mutation in an invader could account for a particular time lag, and that evolution in general could greatly change the impacts of an introduced species. In no instance can a sudden increase in population size and impact of an introduced species be clearly attributed to a mutation, but there is ample evidence that such species evolve in their new homes. How frequently and to what extent does such evolution change their impacts?

Morphological evolution of introduced species is often apparent. The small Indian mongoose, whose depredations of native island species were discussed earlier, has become larger and more sexually dimorphic on all islands to which it has been introduced. This change is probably selected for in the absence on the islands of the slightly larger gray mongoose (*Herpestes edwardsii*), with which the small Indian mongoose coexists in the region of origin for the island populations (Simberloff *et al.*, 2000). The North American muskrat (*Ondatra zibethicus*), introduced as a fur bearer to Europe in 1905, has spread throughout much of Europe in less than a century. The muskrat is well known in its native range as a species with substantial variation in morphology (especially size), to the extent that many subspecies have been named. In Europe, it has already evolved approximately the same degree of variation (Pankakoski, 1983). Similarly, the European house sparrow (*Passer domesticus*) was introduced in New York City in 1853 and quickly spread to become one of the most common birds in North America, covering much of the continent. It has evolved so much that distinct "races" are now easily identified in different parts of its introduced range (Johnston and Selander, 1971). Many plant species are known to differ substantially between their native and introduced ranges, though there is generally far less evidence than in the vertebrate cases just cited that the differences are genetic. What is rarely known in these demonstrated instances of evolution after introduction is how these changes affect the impacts of these species on native communities and ecosystems.

In agroecosystems, however, good evidence of increased impacts generated by gradual evolution within introduced species is found among several insect pests of agriculture. For instance, the southern cowpea weevil, *Callosobruchus maculatus*, is native to sub-Saharan west Africa but has become a worldwide pest of legume seeds. The original host was the wild progenitor of black-eyed peas in Africa, but the weevil has now evolved biotypes that thrive on at least 12 species of crop beans, with increased survival on the new host plants (Wasserman, 1986). The western corn rootworm, *Diabrotica virgifera*, is native to Central America and invaded North America by the early twentieth century. In response, farmers adopted the tactic of rotating corn with soy. However, recently a biotype has evolved that prefers to oviposit and feed on soy, and genotypes have also evolved with extended periods of diapause, so they can survive the rotation period with soy and attack the next corn crop (Levine *et al.*, 2002).

The hybridization of an introduced species with a native one can bring in new genes that can increase impact and can even lead to the formation of a new, more invasive species. For example, North American cordgrass (*Spartina alterniflora*), introduced in shipping ballast to southern England, occasionally hybridized with a noninvasive native congener, *S. maritima*. These hybrids were sterile, but eventually one hybrid

individual underwent a doubling of chromosome number to produce a fertile new species, *S. anglica*, which turned out to be highly invasive (Thompson, 1991).

The coevolution of the introduced rabbit and myxoma virus in Australia and Great Britain certainly affected the impact of the rabbit on native systems. The fact that the rabbit became somewhat more resistant to the virus, and that the virus evolved to be somewhat more benign, lowered the rabbit mortality in each successive epizootic, thus the degree of various impacts outlined earlier. Because pathogens and their hosts often coevolve, changes of impact might be expected. They are not always seen, however. Chestnut blight has not yet become perceptibly less devastating to American chestnut, and only one native Hawaiian bird has evolved any traits conferring resistance to avian malaria.

Many introduced pest insects have evolved resistance to chemical pesticides and thus generated much greater impacts, generally on agricultural or silvicultural plants. Just as strains of human pathogens have evolved resistance to whole sequences of antibiotics, some pest insects have evolved resistance to several insecticides. This resistance can arise in three ways: insects can evolve to tolerate greater amounts of the chemical, they can evolve physiological means of detoxifying the chemical, or they can evolve behavioral traits (such as going to the bottom of a leaf instead of the top) that help to avoid contact with the chemical. Introduced weedy plants also evolve resistance to herbicides, though this phenomenon has not been as widely studied as insect resistance.

The evolution of resistance to chemicals by introduced pests gives impetus to the desire to control them biologically, through the introduction of natural enemies. However, this approach has fostered concerns about subsequent evolution. For pathogens, one concern is that the target organisms will evolve resistance to them. Much of the market for insect pathogens today consists of products involving two organisms, the bacterium *Bacillus thuringiensis* and heterorhabditid nematodes. Both types have no natural association with insect pests on plants and thus must be routinely reapplied. It is possible that target pest insects could become resistant to them, simply through repeated exposure plus selection of resistant strains. This possibility is heightened for the bacterium by the fact that *B. thuringiensis* toxins are now being genetically engineered into crop plants, thus increasing exposure of pest insects to them and increasing the rate of natural selection for resistance. However, introduced biocontrol insects can evolve greater adaptation to a potential host and thus become more rather than less lethal. In the US, the Egyptian alfalfa weevil, *Hypera brunneipennis*, was originally quite immune to the European ichneumonid parasitic wasp *Bathyplectes curculionis*, encapsulating 35–40% of the eggs and larvae in an immune response. Fifteen years later, only 5% of the eggs were encapsulated (Messenger and van den Bosch, 1971).

A second concern is that introduced biological control agents could evolve to switch hosts. For introduced insects, the fact that host range can be controlled by a single gene only heightens this concern, as does the fact that certain features of most biological control introductions favor fast evolution. These features include initially small population size, rapid population growth in new environments, and novel, abundant resources. In light of the possibility, it might seem

surprising that few examples of host-switching are known. Because many of the pathogens used or contemplated as biological control agents have broader host ranges than parasitic insects, the probability of host-switching accompanied or followed by evolutionary adaptation to the new host is enhanced.

The introduction of new individuals of a native or previously introduced species can bring new genes that enhance the impact of that species, sometimes dramatically. For instance, common reed (*Phragmites australis*) has been present in the US for thousands of years. In the last 150 years it suddenly became highly invasive in wetlands, with its geographic range and abundance greatly increasing. This expansion arose from the arrival, probably in soil ballast of ships, of a non-native genotype that has both displaced native genotypes and spread to areas not formerly occupied by the species (Saltonstall, 2002). Reed canary grass (*Phalaris arundinacea*) similarly spread rapidly in North America after multiple introductions from Europe bearing new genotypes (Lavergne and Molofsky, 2007). The introduced European green crab (*Carcinus maenas*) spread further north along the eastern coast of North America after new genotypes arrived in the 1980s, probably in ballast water, and proved more cold-tolerant than the previously introduced ones (Roman, 2006).

Quantifying Impact

“Impact” and “effect” have never been formally defined in invasion biology, so that rankings of introduced species in terms of greatest impact are impressionistic. Area of occupancy is a frequently used index of effect, although the number of individual invaders per unit area and what each individual actually does would be important (though more difficult to measure). Impacts on ecosystem processes, such as nutrient cycling and fire frequency, are seen by some biologists as the best measures of effect of introduced species, on the grounds that such alternation of processes could affect a large number of species simultaneously. Both areal coverage and impact on processes often envision outcome for native species, communities, and ecosystems as the crucial measure of impact. The real impact, in these terms, would require accurate knowledge of the range size of the species, the distribution of abundances of species within this range, and the impact on the native species, both on-site and elsewhere, per individual invader (or per unit biomass of the invader) (Parker *et al.*, 1999). The first two factors can be measured or at least estimated in straightforward fashion, although the effort for some species would be enormous. The per capita impact, however, would probably entail not only detailed observation but also experiment, perhaps long-term, at individual, population, community, and ecosystem levels. As one example of the subtleties that might be involved, the fact that an introduced predator is observed to eat individuals of a native species does not necessarily mean that this predation affects the population size, behavior, or ecology of the prey species. Ecological methods are well enough developed that these sorts of questions can be answered, but they generally require detailed research, not quick observation.

Economic costs of an invasion are often proposed as estimates of the impact of introduced species, but these costs are more easily tallied from a human standpoint than from that of native species, communities, and ecosystems. It is a fairly straightforward matter to tabulate the costs expended in controlling a particular weed or insect pest, in terms of materiel and personnel used. And one could relatively easily add the monetary cost of many services or goods lost because of an introduced species – say, a percentage of some crop. Costs of other lost services are not so easily tabulated, even in human terms. For example, how expensive is the loss in enjoyment suffered by citizens who can no longer walk through Fraser fir or American chestnut forests in the eastern US because these were eliminated by introduced species? Economists have attempted to measure these costs. For example, travel-costs of citizens to a particular natural site, as evidence of how much they are willing to pay for such an experience, are sometimes used to estimate the “value” of a site, at least to humans. But all of these methods are controversial. And costs to nonhuman species are even harder to weigh in monetary terms. What was the cost, in dollars, to the insect species extinguished because of the chestnut blight?

In sum, even though a bewildering variety of impacts of introduced species can be demonstrated, measuring and comparing these impacts for different species remains as much a conceptual and practical challenge as predicting them does.

Glossary

Local population That part of the population of a species found in a particular habitat patch.

Metapopulation The collection of local populations in a region.

Patch An area of suitable habitat for a particular species or particular collection of species, ideally bounded by unsuitable habitat, or habitat with different physical properties. Normally one of many such areas in a region.

Spatially structured population A population whose reproductive and survival rates vary over the region that it inhabits reflecting variation in the physical and biological properties of the localities within the region.

Strict metapopulation (Also called a “classical metapopulation.”) A metapopulation satisfying the following conditions:

1. Local populations are partially isolated from one another and are frequently capable of sustaining themselves for several to many generations in the absence of immigration from other local populations.
2. Local population extinction occurs on a time scale of several to many generations.
3. Migration between local populations leads to reestablishment of local populations following local extinction.

Outline

The study of metapopulations is concerned with the patchiness of populations in space, and the role of this patchiness in population dynamics, population stability, coexistence of species, and the maintenance of diversity. Strict metapopulation studies focus on patchiness due to colonization and extinction of local populations in a region. They have important applications in conservation biology, especially concerning the effects of habitat fragmentation. Studies of metapopulations, and their generalization to spatially structured populations, emphasize that patchiness markedly alters population dynamics and the outcomes of species interactions. These findings have implications for the concepts of equilibrium, nonequilibrium dynamics and population regulation, and hence for management practices influenced by these concepts.

Introduction

The concept of a metapopulation has its beginnings in the suggestion of Andrewartha and Birch and others that some, if not most, local populations of organisms in nature, frequently go extinct, and are re-established later by immigration from surrounding areas (Hanski, 1999). The metapopulation – the collection of all local populations – only persists if local extinction is balanced by recolonization. How this balance is achieved is an important focus of metapopulation theory. Because many human activities fragment natural habitats, humans may artificially create metapopulations or may decrease the density of local populations within existing metapopulations, and may put the continued survival of natural populations at risk. Hence metapopulations are a major topic in conservation biology. Regardless of whether a natural population is distributed over easily defined patches of habitat on which distinct local populations may be recognized,

essentially all natural populations are patchily distributed in space, and most ecologists believe that patchiness in space and time has functional roles in population dynamics, i.e., in the manner in which population densities change over time. Most important, population dynamics at the regional or metapopulation scale are affected by the patchiness of the populations and their physical environment at lower spatial scales.

One very obvious way that patchiness is important is through mate finding. A sparse population evenly distributed over an area may have a low reproductive rate because males and females encounter each other too infrequently for many eggs to be fertilized, or flowers pollinated. Patchiness can be a solution to this problem. High local concentrations or aggregations of a species remove the problem of low encounter rates of males and females consistent with a low average density. Similar effects occur from predation. Individuals may find safety from predators in a group but be vulnerable when isolated. Such effects of sparse populations are called Allee effects and are potentially one reason why patchiness in space is important. However, disadvantages from clumped distributions in space might occur too, for example, due to competition. Clumps of individuals in space deplete resources locally and reduce population growth rates over what would be experienced were the population more evenly distributed. A similar effect results if predators are attracted to clumps of prey. Rather than prey finding safety in numbers, it is possible that they may be more vulnerable in clumps if predators are able to build up in numbers at clumps of prey.

These explanations for the importance of patchy distributions involve interactions between organisms in the same species, and therefore involve density dependence: dependence of the probability that an individual survives, or dependence of its reproductive rate on population density. The most striking theoretical predictions for the effects of patchiness, however, are for interactions between species, one or more of which is patchily distributed. Major effects of

patchiness on population dynamics also arise from spatial and temporal variation in the physical environment. Naturally, if species are concentrated in better localities, they will have higher growth rates in comparison with random distributions, but such environmental variation has its most striking effects by altering the interactions between organisms, locally in space, and hence by altering the collective outcome of those interactions at the level of regional populations. These ideas are all studied within the context of metapopulations, but extend to spatially structured populations generally (Chesson *et al.*, 2005). Metapopulation concepts were originally developed with terrestrial systems in mind (Hanski, 1999), but these ideas have been strongly embraced to understand the ecology of marine systems as well (Kritzer and Sale, 2006).

Strict Metapopulations

The idea of a metapopulation is most commonly invoked when patchiness in space is so extreme that the regional population splits into local populations, each of which is too small to persist indefinitely (Hanski and Gilpin, 1997; Hanski, 1999). Local populations go extinct, but may be recolonized by migration from other local populations. In the strict sense of a metapopulation, local populations are sustained primarily by reproduction of resident individuals but may be subsidized by infrequent immigration from other local populations. The role of immigration, however, is seen mainly as allowing recolonization of a local population after it has become extinct. Local extinction may occur for any of a variety of reasons, as discussed below, but is normally assumed to occur asynchronously in different local populations, or the metapopulation as a whole would be lost. Although nearly all organisms are patchy in space, there is some question of how frequently all the above details of a strict metapopulation are satisfied. Thus, in considering the results of metapopulation theory it is important to distinguish those features applicable only to strict metapopulations, and those applying more generally to spatially patchy populations.

Single Species Considerations

The main interest in metapopulations, strictly defined, is with colonization and extinction dynamics. The variable of prime concern is the proportion, p , of patches (places where a local population potentially could exist) that are occupied by the species. Two parameters are involved with the dynamics of this occupancy fraction: the extinction rate of local populations, ε , and the rate c at which empty patches are recolonized, per fraction occupied. In essence, the fraction of local populations going extinct in one unit of time is ε . The probability of an extinct population being recolonized in one unit of time is cp , because c is measured proportional to the fraction of occupied patches and incorporates the idea that the probability of recolonization should depend on the fraction of other patches that are occupied. Thus, the change in the fraction occupied with time may be expressed as the following differential equation, called the Levin's equation

$$\frac{dp}{dt} = cp(1 - p) - \varepsilon p$$

If the rates ε and c remain constant with time, it follows that in a metapopulation with a large number of local populations, the fraction occupied will come to an approximate equilibrium at the value $1 - \varepsilon/c$, provided $c > \varepsilon$, because at this value extinction just balances recolonization. If ε is greater than c , local extinction exceeds local colonization and the metapopulation as a whole goes extinct. Conversely c must exceed ε for the metapopulation to persist. This result is often called the threshold condition, and is of major concern for applications of metapopulation theory in conservation. Because actual metapopulations in nature never have infinitely many local populations, the system is never exactly at the equilibrium $1 - \varepsilon/c$, but may fluctuate around this value. In metapopulations with only a few local populations, there is a danger that all local populations will simultaneously go extinct, causing the extinction of the metapopulation even though $c > \varepsilon$.

On what biological features do these colonization and extinction rates depend? Consider extinction. Local extinction can occur in many ways, some of which stem directly from the activities of humans in habitat destruction or modification and hunting, but the interest in metapopulation models is the case where local extinction is a natural and repeated phenomenon, whose rates may be influenced by human activities, but whose presence is not. Thus, local populations may become extinct by chance because of small population size. The phenomenon of demographic stochasticity refers to independent chance events in the lives of individual organisms. It is impossible to predict how long any individual will live, and how many offsprings it will have, and these effects summed over individuals in a population cause it to fluctuate. In a small local population, there is always a definite probability of below replacement reproduction in any year; and in a small population, a chance run of such years can lead to extinction. These probabilities drop off dramatically as population size increases, but there are other means that can also lead to local population crashes, including unstable population dynamics and disturbance.

Two different forms of disturbance are commonly considered. An environmental disturbance is caused by an environmental event such as a storm or fire, and a biological disturbance is caused by the invasion of predators or disease. In the strict metapopulation scenario, the interest is in disturbance events that lead to extinction of the local population either coincident with the disturbance or shortly after, following weakening of the population by disturbance. At any time, disturbances must strike patchily in space to cause extinction of only a proportion of local populations, or the metapopulation as a whole would be lost. It is very common for environmental disturbance agents such as fires and storms to distribute mortality very patchily in space even though they may affect a large area in a short period of time.

In a strict metapopulation, to which Levin's equation applies, recolonization of a patch is from immigration from occupied patches. Many organisms may have means of recovering from disturbance by regrowth from seeds, roots, resting eggs, or spores within a recently disturbed patch, but with a strict metapopulation, such populations have not gone extinct. They have merely died back, and regenerate from dormant stages or below ground parts. The strict metapopulation idea that

colonization is from external sources is the reason for the formula cp for the recolonization probability. Regeneration from sources within a patch should not depend on p . Confusing regeneration with recolonization could potentially lead to serious errors in calculations and inferences.

Recolonization can be from mobile individuals, seeds, spores, or other propagules that arrive from external sources in sufficient quantity to re-establish a local population. The value of c will be affected by a variety of factors such as the spacing of local populations. With large distances between local populations, many propagules may perish after leaving their source population before arriving in suitable habitat. The sizes of local populations will also influence c because larger local populations should be expected to send out more propagules. The size of the metapopulation, in terms of the number of local populations, is also important. Because the number of habitat patches is always finite, the fraction of patches occupied is not at the equilibrium value $1 - \varepsilon/c$, but fluctuates around this value; the smaller the number of habitat patches, the larger these fluctuations. If the number of habitat patches is too small, there is a danger of simultaneous extinction of all local populations eliminating the metapopulation even if $c > \varepsilon$.

Habitat fragmentation by human activities may lead to a metapopulation structure of local populations even if that were not the pre-existing situation for the natural population of these organisms. With continuing habitat destruction, c will decline due to increased spacing and smaller size of suitable patches, with the danger that c will drop below ε , especially as ε itself may increase as suitable patches decrease in size and support smaller local populations. Thus, the danger exists that even though there is habitat capable of sustaining local populations, local populations may be either small or so vulnerable because of other habitat alterations that the rate of local extinction exceeds local recolonization, which would lead to loss of the metapopulation altogether. Alternatively, if the organisms are not able to disperse between habitat patches, habitat fragmentation is not accompanied by positive colonization rates, and the metapopulation heads to extinction at the rate ε the moment it is created.

The simple destruction of habitat reduces natural population sizes, putting species at risk independently of these metapopulation considerations, but metapopulation theory emphasizes that the viability of populations in the remaining habitat may be seriously affected by its connectedness. A final feature of habitat destruction is that by reducing the areal extent of a population, it increases the probability that extinction events occur simultaneously in different parts of the metapopulation. For example, fire might sweep through the whole area occupied by the metapopulation, or climate fluctuations might have severe effects in all parts of the metapopulation, endangering the metapopulation as a whole.

So far, the rates c and ε have been treated as though they are independent of p , the fraction occupied. This need not be the case. It has been suggested, for example, that extinction rates may decrease as the fraction occupied increases because extant local populations may tend to be higher and less vulnerable to extinction when they are subsidized by immigration. This could be especially important in the recovery of local populations after chance population declines, staving off extinction.

For this reason, this phenomenon is called the rescue effect. If the rescue effect is required for c to exceed ε , the metapopulation as a whole may be especially vulnerable to extinction due to chance fluctuations in the fraction occupied, for if this fraction falls too low ε will exceed c promoting further decline and total extinction of the metapopulation.

There are many other details and complications that one can consider in single-species metapopulations such as variation in the sizes of local populations, their distances apart, and variation in habitat quality, features that are discussed in several excellent books on the subject (Hanski and Gilpin, 1997; Hanski, 1999; Hanski and Gaggiotti, 2004; Kritzer and Sale, 2006). These complications, naturally lead to much more complex equations than the Levin's equation given here. The fraction of patches occupied is no longer the key variable in the equations. Instead it is replaced by the probability, unique for each patch occupied. Under certain conditions, this probability is equal to the incidence of occupancy of the patch, which is defined as the fraction of time that the patch is occupied (Hanski, 1999). These sorts of modifications are especially useful when metapopulation theory is applied to a particular natural system when the reality of nature's complexity must be confronted (Hanski and Gaggiotti, 2004).

Multispecies Considerations: Predators and Parasitoids

Extinction and colonization rates may depend on other organisms. Indeed, as mentioned above, local extinction may be a consequence of invasion of the local population by predators or disease. In this case, extinction rates vary with the abundance of predators within the metapopulation, which in turn depend on the abundance of the prey itself. It is quite possible that only the prey has a metapopulation structure, because predators may be more mobile occupying all of the landscape. Their density must be taken into account in determining the extinction rate of the prey but otherwise their inclusion does not lead to major differences in the understanding of metapopulation dynamics, except potentially in terms of the effects of habitat destruction, as discussed below.

If both predator and prey have the same metapopulation structure, a metacommunity results (Holyoak *et al.*, 2005). Simple models of isolated local predator-prey communities are often unstable, causing large fluctuations in their abundances and potentially leading to extinction of the prey or the predator (see Figure 7). A metacommunity structure has long been suggested as one means by which predator-prey interactions may be stabilized in nature. The interaction between the two locally in space remains unstable: the prey is driven extinct by the predator, but provided the colonization rate c for the prey exceeds its extinction rate due to predation and other causes, it is able to persist in a metapopulation. Similarly, although the predator depends on the prey whose local extinction leads to local predator extinction, provided the predator can find patches sufficiently well, it can persist in the system also. In this way, it is possible for predator and prey to have a stable equilibrium at the metapopulation level in spite of what might be unstable dynamics on the local scale (Nee *et al.*, 1997). This metacommunity structure may have important conservation implications. Habitat destruction may

more strongly affect the predator than the prey because prey numbers in a region may be buffered at first by reduction in predator numbers, with the effects of habitat destruction on prey being stronger after the predator has been eliminated (Nee *et al.*, 1997).

The potential for metacommunity structure for predator and prey is also of great interest in the study of biological control of insect pests and introduced weeds. Commonly, in biological control, one seeks as a control agent a predator or parasitoid (a parasite that invariably kills parasitized hosts) that is specialized on the pest organism and causes sufficient damage to the pest to reduce its number greatly. Such a control agent, however, may have an unstable interaction with its host, leading to large oscillations in agent and pest densities, an undesirable outcome. However, there are many successful examples of biological control where the pest is maintained at low relatively and stable numbers. One candidate explanation for such control is that local population dynamics are indeed unstable, but regional dynamics are stable because they are metapopulation dynamics (Briggs *et al.*, 1999).

Multispecies Considerations: Competition

One organism may cause another to go locally extinct, not because it is a predator of that other organism, but because it is a competitor. Many years ago, G.E. Hutchinson and J.G. Skellam suggested that inferior competitors may persist regionally by being good colonizers of newly vacant habitat, where they persist only until their competitors find that habitat and drive them extinct. They termed such good colonizing inferior competitors “fugitive species” (Hanski, 1999). An essential component is a tradeoff between dispersal ability and competitive ability: If the better competitors were not poorer colonizers they would arrive too quickly in vacant habitat, giving insufficient opportunity for exploitation of that habitat by fugitives.

The fugitive species idea has been extended in recent years to consider the possibility that a suite of competitors in a system might have a competitive hierarchy, i.e., be strictly ranked in competitive ability with better competitors eliminating poor competitors whenever they occur in the same patch (Hastings, 1980). Such a competitive hierarchy prevents long-term coexistence in any patch, but if all local communities are ephemeral because disturbance takes place locally in space and removes whatever species happen to be there, then every so often any given local community becomes available for colonization by even inferior competitors. Colonization events in the presence of a competitive hierarchy drive succession (a change in species composition in a particular direction) within a local community toward domination by the best competitor. Assuming that inferior species have higher dispersal rates, then they have a higher probability, per unit occupancy (per unit p), of arriving in vacant habitat. Any species could actually arrive first, but inferior competitors have an arrival advantage. Any species arriving at a site that is a superior competitor to the current occupant takes that site. The local community shifts progressively in the direction of the best competitor in the system until disturbance occurs, interrupting the process and starting it all over again.

Because both extinction and colonization occur patchily in space and time, the metacommunity consists of a mosaic of local communities in different stages of succession (Figure 1). Each local community may have low species diversity because only the best competitor in the local community persists there for long. However, when summed up over space, the metacommunity has high species diversity due to the fact that different local communities are in different successional states and have different species. It is possible for the metacommunity to be in equilibrium, and maintain this high species diversity regionally. This equilibrium is dependent on the inverse ranking of competitive ability and colonizing ability, but it is not sufficient for an inferior competitor simply to be a

Figure 1 Turnover of species in a subset of the patches of a metacommunity with successional mosaic dynamics. Three different species are indicated by the symbols ●, ■, and ▲ in order of decreasing competitive ability and increasing colonizing ability. Blank means an empty patch.

better colonizer: it has to be better by more than a critical amount that depends on the colonizing abilities of superior competitors, and the disturbance frequency (Hastings, 1980).

The disturbance frequency has a particularly important role in the maintenance of regional diversity. A higher disturbance frequency means fewer patches have the best competitor and more patches are available for other species. At too low a disturbance frequency, lower ranked species do not have sufficient opportunity for colonization and therefore may not persist regionally: their ε values may exceed their c values. However, at higher disturbance frequencies, lower ranked species may persist and coexist regionally with higher ranked species. If the disturbance frequency is too high, the best competitors, which are by assumption poorer colonizers, have too high an extinction rate, ε , relative to their colonization rate, c , and disappear from the system. At extreme levels, only the very best colonizers can persist. It follows that with such competitive hierarchies, both high and low disturbance frequencies lead to low regional diversity. Diversity is maximized at some intermediate value of the disturbance frequency, an idea that is often referred to as the *intermediate disturbance hypothesis*. Disturbances here can be of the physical sort or of the biological sort provided the predators or other agents bringing about disturbance are generalists, and therefore are dependent for their own persistence on all species in the system, not just particular species, which they may control separately from other species. Specialist mortality agents may be important in the maintenance of diversity (Chesson and Huntly, 1997) but this idea is not the intermediate disturbance hypothesis.

The critical feature of the above mechanism of diversity maintenance is a metacommunity that exists as a successional mosaic, i.e., the system is diverse because local communities range over a variety of successional stages having different species that provide colonists of other local communities. Colonization moves succession along or re-establishes local communities following local disturbance (Chesson and Huntly, 1997). This successional mosaic model has been suggested to work with local populations consisting simply of single individuals, for example, single herbaceous plants in a meadow (Lehman and Tilman, 1997). Although this is not exactly what one might think of as a local population, the same principles apply. Death of an individual is then equivalent to local population extinction. Death of an individual may be brought on by the arrival of a superior competitor at the site, disturbance, or simply senescence. Disturbance or senescence open the site to invasion by any species. Otherwise the site can only be invaded by a superior competitor. The idea that many species may coexist in an area by this mechanism operating on a small spatial scale is referred to in the literature as coexistence by competition-colonization tradeoff. This idea is particularly useful in the case of plants or sessile aquatic animals that hold space (Lehman and Tilman, 1997).

These ideas on diversity maintenance in metapopulations have important implications for conservation. If habitat destruction lowers colonization rates, as discussed above, competitively superior species may be most at risk (Tilman and Lehman, 1997) because of their already poor colonizing abilities making them less tolerant to decreases in

colonization rates. These models predict that habitat destruction eventually negatively affects all species, however. When the per unit colonization rate, c , of the best colonizer, is reduced below the extinction rate of local populations, all species are doomed to regional extinction even though patches of suitable habitat remain.

Quantitative Effects of Spatial Variation

The discussion so far has made the assumption that the only thing we need to know about a local population is presence or absence: is it extinct or not? This is crude accounting, for surely the number of colonists or propagules sent out by a local population depends on how large that local population is. Patches may be of different sizes and qualities, and therefore support local populations of different sizes and densities, issues that are active areas of research in metapopulation theory (Hanski and Gilpin, 1997). Moreover, local populations vary in size over time in any one patch, and in space from patch to patch even when patches of identical size and quality are compared. Ignoring changes in local abundance over time (i.e., ignoring the dynamics of local abundance) would be justified if local population build up after colonization occurred quickly to some local population equilibrium (a population size at which on average, reproduction and immigration balances deaths and emigration), about which population fluctuations occur until extinction. A broader variety of behaviors of metapopulations can be examined by taking actual local population sizes into account (Chesson, Donahue, Melbourne, and Sears, 2005). In general there is also no reason to restrict consideration to the situation where local populations are defined by discrete habitat patches. Indeed, a variety of techniques exist to study populations that vary continuously in space (Bolker, 2004).

These more general approaches explicitly incorporate the statistical properties of spatial variation of specific relevance to understanding the change in the nature of population dynamics as the spatial scale changes, in other words, the scale transition. These statistical properties are most simply understood in terms of particular variances and covariances in space of population densities, environmental characteristics, and population growth rates. Of particular note is fitness-density covariance (Chesson *et al.*, 2005). This quantity is the covariance in space between the relative density of a local population (local density divided by the spatial average density) and the average fitness of the individuals of a species in that local population. Fitness is defined here as the contribution of an individual through reproduction and survival to the metapopulation as a whole. Fitness-density covariance reflects the extent to which a population is concentrated in favorable locations and defines exactly how much this unevenness of distribution affects the growth rate of the whole metapopulation. Understandably, a population that is more concentrated in favorable locations will grow faster.

Fitness-density covariance, however, is but one aspect defining the change in population dynamics with the change in scale (the scale transition), and indeed, it is just one way of understanding the scale. Fundamental is the interaction between nonlinearities in population growth and spatial

variation. Illustrations of this key concept are given below. It is easier to understand by maintaining the approximation or fiction that space can be divided up discretely, with two relevant spatial scales. The smaller scale is the spatial scale on which interactions between individual organisms occur, i.e., it is the spatial scale of positive and negative density-dependent effects within species, the scale of competition between species and the scale of predation, whichever of these are important in the system of concern. This scale corresponds to the local population scale in the strict metapopulation sense, and shall still be referred to in terms of the patch and the local population. The larger scale is the scale of the whole population, which corresponds to the metapopulation or regional scale in the discussion above.

Single-Species Dynamics

To introduce the fundamental concepts, consider first of all density-dependent population dynamics applicable to organisms with annual life cycles. The dynamics of a local population in the absence of migration can be defined by plotting local population density (numbers per unit area), N_{t+1} , at time $t + 1$, as a function of its density, N_t , the previous year, as represented in Figure 2. These curves are dynamical relationships, i.e., by applying them repeatedly, one can plot density as a function of time (Figure 3). The straight line (relationship I) represents the density-independent case where individual organisms do not interact with one another, and so an individual's contribution to future generations is independent of the number of other individuals. Thus N_{t+1} is simply proportional to N_t . Relationships II and III are two cases of density dependence and this density dependence means they are nonlinear, i.e., they are curved or humped relationships – certainly not straightlines. For relationship II, the resources sustaining a local population are strictly limited, fixing an upper bound on the local population density, which is achieved if the resources are efficiently utilized. The larger the population at time t , the closer the population comes to using

all resources and the closer the upper bound on population density is approached. Annual plant populations commonly accord at least approximately with this relationship, which is sometimes referred to as contest competition. Some insect populations may have dynamical relationships more like curve III. Above a certain density, the number of insects in year $t + 1$ is a decreasing function of the number of insects in year t . One explanation for a relationship like this is so-called scramble competition: at high densities, a high proportion of the population may starve to death, which leads to loss of the resources that these individuals consumed before death. Thus, a large fraction of the resources that could have been turned into new individuals at time $t + 1$ is lost, and the population crashes.

The three different dynamical relationships of Figure 2 give very different local population dynamics (Figure 3). The linear case, relationship I, gives simply geometric increase. Relationship II (contest competition) gives highly stable dynamics: the population quickly converges on an equilibrium population size, which is determined by the point at which the diagonal line in Figure 2 intersects the dynamical relationship. Relationship III (scramble competition), however, gives irregular fluctuations referred to as deterministic chaos, which result here from the tendency of scramble competition to cause population crashes following population buildup. What happens when local populations with these various dynamics are connected regionally? If there is no variation in population density in space, then regional population dynamics are the same as local population dynamics. However, if there is a large amount of spatial variation in population densities (a common occurrence in nature), regional population dynamics can be very different from local dynamics (Figure 4). The density-independent case (relationship I), however, does not show different local and regional dynamics because individuals are not affected by density, and so population dynamics cannot be affected by spatial variation in density. On the other hand, the strong density dependence arising with scramble competition leads to correspondingly striking differences between regional and local dynamics. For the situation depicted, which is defined in detail below, chaotic fluctuations have been replaced

Figure 2 Solid curves: dynamical relationships of single-species local populations, I density-independent dynamics, II contest competition, III scramble competition. The equilibria are the intersections of these curves with the dashed line defining no change in local population size ($N_{t+1} = N_t$).

by a stable equilibrium. For contest competition (relationship II), the effect of spatial variation on regional population dynamics is quantitative not qualitative: the equilibrium density is lowered.

What is the explanation for these changes in dynamics at the regional level in density-dependent situations? To answer this question, we need to work out the dynamical relationship between $\bar{N}_{t+1}$ and $\bar{N}_t$ defining the dynamics of population density at the regional level. These regional densities can be defined as the averages of the population densities in local populations, weighted if necessary by patch area. Dynamical relationships like those in **Figure 2** continue to define dynamical change within patches, but disturbance and fluctuations due to small population size lead to random deviations about these relationships. Thus, these local dynamical relationships are just mean relationships converting inputs of population density into outputs and some of the output population in any patch may then disperse to other patches.

The essence of the difference between local and regional dynamics can be understood by imagining that dispersal occurs early each year, and for the rest of the year, patches are isolated with mean change governed by dynamical relationships in each patch. Further imagining that after dispersal local populations exist at just two densities, high and low, in equal abundance, then the regional dynamical relationship is easy to derive. This is done in **Figure 5**, where it is assumed that low density patches have inputs $1/3$ the regional density, $\bar{N}_t$, and high-density patches have inputs $5/3$ of $\bar{N}_t$. The solid curve defines the relationship of local outputs to local inputs (scramble competition) and the dashed curve then defines the relationship between $\bar{N}_{t+1}$ and $\bar{N}_t$, i.e., the regional dynamical relationship. This regional relationship is found by connecting pairs of points on the local relationship, corresponding to low and high-density inputs, and finding the midpoints of the lines joining these pairs of points. For example, the points A and B of **Figure 5** are one such pair of points, and M is their midpoint. The x coordinate of M is thus the regional input, $\bar{N}_t$, which is the average of the x coordinates (local inputs) of

Figure 5 Construction of the regional dynamical relationship from the local dynamical relationship III of **Figure 2** and spatial variation between two densities. Solid curve: local dynamical relationship. Thick dashed curve with + symbols: regional relationship.

A and B. The y coordinate of M is the regional output, $\bar{N}_{t+1}$, which is the average of the y coordinates (local outputs) of the points A and B. The complete regional relationship is found by repeating this procedure for every possible value of the input density $\bar{N}_t$.

Comparison of the points M on the regional relationship with the point M' on the local relationship reveals the reason for the difference between local and regional relationships. These points both have the same input density, but M' is the output of the local dynamical relationship, whereas M comes from averaging the outputs of the local dynamical relationship at two different input densities, which give outputs less than M' due to nonlinearity (curvature) of the local relationship. Thus, nonlinearity in the local dynamical relationship combines with variation in local inputs reducing the hump on the regional dynamical relationship. A similar effect acting on the nonlinearity in the local dynamical relationship after the hump reduces the severity of the decline in the regional dynamical relationship, and it is the combination of these two effects that is responsible for the strong stability of the regional dynamics shown in **Figure 4**. Nonlinearity and spatial variation also affect regional dynamics in the case of contest competition but there the effects are quantitative, not qualitative. The regional relationship for contest competition is shown in **Figure 6**, where it is assumed that 50% of local populations are extinct, and the others have a density twice the regional density. Unsurprisingly, the regional equilibrium is 50% of the local equilibrium, but this reduction, and the regional relationship in total, can be understood using the same averaging approach discussed here for scramble competition.

Having local populations take on just two densities for any given average density is clearly unrealistic. However, the qualitative features of the results above occur with general sorts of variation commonly observed in natural populations. The most common situation in nature is a negative binomial distribution of possible local population densities, which means that densities are somewhat more clumped than random in space. The striking change in dynamics from regional to local found for scramble competition occurs in enhanced

Figure 6 Construction of the regional dynamical relationship from the local dynamical relationship II of **Figure 2** in the presence of spatial variation between two densities. Solid curve: local relationship. Thick dashed curve, regional relationship.

form in that case (Chesson 1998). In the density-independent case (relationship I) the dynamics at the regional level are unaffected by variation from patch to patch: M always equals M' , regardless of the pattern of variation. The nonlinearities, i.e., the deviations from a straight line relationship, present in relationships II and III, are necessary for variation in space to have an effect on the dynamics of regional density, and these nonlinearities arise from density dependence.

There are many causes for spatial variation in local densities of which disturbance and fluctuations due to small population size are mentioned above. Simple random dispersal processes also lead to some variation in density, but spatially varying environmental factors may have large effects on dispersal, and on the ultimate distribution of organisms among patches. For example, in marine organisms, such as reef fishes, local currents may transport larvae away from some places and toward others, and these currents may vary with time of year, storms, and other atmospheric conditions, potentially delivering dispersing larvae to reefs in a very patchy fashion. Moreover, organisms commonly actively seek particular places, and the relative attractiveness of different places may vary greatly. Organisms may also seek out their own species, and so any existing spatial variation in density may be magnified by later dispersal. Unstable population dynamics occurring locally in space can itself be a cause of local variation in density, at least in models. In the illustrations here, spatial variation in density was assumed to have a fixed relationship to regional density (e.g., low-density patches $\bar{N}_i/3$, and high-density patches $5\bar{N}_i/3$). More realistically, local densities will not have fixed relationships to the mean, and therefore the regional relationship will in fact change over time as the relationship between spatial variation and regional density changes (Chesson, 1998). Nevertheless, the way in which nonlinearity and spatial variation change the regional relationship, illustrated in Figs. 5 and 6, remains the same in spite of all these complications. In particular, the stabilizing effect of spatial variation in densities on scramble competition continues to be seen in much more complex circumstances than illustrated here.

These quantitative considerations are very different in spirit from the colonization and extinction issues discussed above for strict metapopulations, but the two approaches can be

related. Colonization and extinction dynamics involve implicit density-dependence: to count all occupied patches as equivalent, recently colonized patches must quickly increase in density to some sort of steady state, such as a local equilibrium density, or fluctuation about a local equilibrium. Local dynamical relationship II would serve in this circumstance, with the mean output taking into account the probability of local disturbance. The specific example above with half the patches extinct corresponds to a c to ε ratio of 0.5.

These quantitative considerations apply also to spatially structured populations that are not strict metapopulations, for example, to situations where recovery after disturbance depends to a large extent on regeneration rather than recolonization, and also to situations where only part of the life cycle is spatially confined. For example, it is very common for marine organisms that live on a reef, intertidally, or on the ocean floor, to have widely dispersing larvae, so that only the adult stage has clear spatial structure (Kritzer and Sale, 2006). The adult may be physically attached to the bottom, as in corals, barnacles, and mussels; or if it remains mobile, it may have a territory or at least a home range that is much restricted in extent relative to the distance traveled by dispersing larvae, as in many reef fishes. Such spatial restrictions mean that interactions between individuals are localized, because the individuals are localized and are most likely most strongly affected by individuals living nearby, for example, on the same coral head or part of the reef. Similarly, in terrestrial plants a spatial unit of major importance is the immediate neighborhood of other plants close enough to compete with it. Insect populations often have spatially confined larvae and dispersive adults. Although it is the adults that disperse in this case, the fundamental principles are the same in all of these cases, and the effects of variation in density in space are similar, even though in no case does spatial structure of one part of the life cycle qualify these populations as metapopulations in the strict sense. The effects of nonlinear dynamical relationships that we have explored above depend on having the smaller scale, which corresponds to the local population in a strict metapopulation, correspond to the scale on which those nonlinear relationships apply. As these nonlinear relationships derive from density dependence, the smaller scale is also the scale of density dependence.

How the scale of density dependence is determined depends on how the individuals in a population affect each other. For example, for territorial coral reef fishes, one source of density dependence may simply be competition for space to set up feeding territories. Other fishes may compete for hiding places from predators. The scale on which fishes may move to secure territories or hiding places defines the scale of density dependence. Predators may cause density dependence in their prey populations by responding to the density of the prey, for example, aggregating in areas of high prey density. The scale of density dependence then is the spatial scale on which predators respond to variation in prey density. Predators may also build up in numbers where prey are dense simply because they have more to eat and therefore reproduce faster. The scale on which this effect occurs is bound to be much larger than the scale of aggregation of predators to variation in prey density. The changes in dynamics with a change in scale demonstrated in **Figures 3–6** should occur in all of these

instances when one compares the dynamics defined on the scale of density dependence with the dynamics that emerge at the regional or metapopulation scale (Chesson, 1998).

Predators and Parasitoids

Like the dynamics of colonization and extinction, a rich array of phenomena is uncovered when the quantitative effects of spatial structure are examined in terms of interactions between species. In particular, predator-prey and host-parasitoid dynamics (Figure 7) are often stabilized by local interactions and spatial variation (Hassell, 2000). This phenomenon is best understood in host-parasitoid systems where a critical issue is spatial variation in the risk of parasitism experienced by a host, which may result from variation in parasitoid density. Figure 8 illustrates how this works. The risk of surviving is thought to be an exponentially decreasing function of parasitoid density, as shown by the solid line. Very simple two-level variation in parasitoids is assumed for ease of illustration: no parasitoids in half the patches, and twice the mean parasitoid density in the other half. The effect of averaging

Figure 7 Host-parasitoid dynamics. Thin lines: local dynamics of an isolated host-parasitoid community in the absence of migration. Thick lines: regional dynamics with parasitoids concentrated in half the patches. Hosts: dashed; parasitoids: solid.

Figure 8 Local host survival rates and regional host survival rates as a function of parasitoid density with half the patches having no parasitoids.

different risk levels, exemplified by Figure 8 is to moderate the decline in host survival with increasing parasitoid density, which means that host crashes following increases in parasitoid numbers are diminished, tending to stabilize the host-parasitoid interaction regionally (Figure 7). Although the reasons for spatial variation in parasitoid density are poorly understood in general, an important feature of predator-prey and host-parasitoid interactions is the potential for the unstable nature of the interactions themselves to generate variation in risk, which may then stabilize population dynamics on the larger spatial scale (Hassell, 2000).

Competitive Interactions

Competition-colonization tradeoffs is one mechanism allowing coexistence of competing species in a patchy environment. Quantitative approaches allow the consideration of other mechanisms and more general spatial variation. Species fail to coexist (i.e., competitive exclusion occurs) when the species best adapted to the environment depletes resources to levels that are too low for other species to persist. Because the environment varies in space, different species may be the best adapted under different environmental conditions. Then many species that depend on the same resources may coexist regionally because each has patches where it is the best competitor, i.e., each has its own spatial niche. If each of these patches were a closed community, i.e., not connected to other places by migration, then just a single species would come to dominate in each locality. However, in the presence of migration, each patch may have many species, because a species that is not the best competitor in that local community has its reproduction supplemented by immigration from places where it is the best competitor.

If environmental characteristics vary over time as well as in space favoring some species sometimes and others at other times, local diversity is even more likely to be maintained at high levels because trends in the local species abundances will be reversed with reverses in the ranking of competitive superiority in a particular locality: species tending toward low relative abundance will be partially restored to higher values. A phenomenon with the opposite effect has been discussed by Rozenzweig (1995), and may be particularly important in animals, especially those with complex behavior. Animals detecting a competitively superior species may leave or keep away from a patch, an effect tending to divide up a landscape into exclusive areas containing only the best species for that area.

These various effects of spatial environmental variation do not require strict metapopulations, but simply spatial structure. This more general theory can be applied, for example, to coexistence of insects, especially various communities of flies, such as *Drosophila* and carrion flies, which lay eggs in ephemeral patches of food, such as fruit, mushrooms, or dead animals. In general, although the larvae of several species are commonly found developing in the same patch of food, it is also a common finding that there is segregation between species in choice of food patches. Although the underlying cause of the choice is not well understood, the effect it has is to promote very strongly stability (Ives, 1988). A second example

of the potential importance of spatial environmental variation is marine communities, especially coral reef fishes, but also various sedentary invertebrates that compete for space, with similar effects applicable to plant species. In marine communities as discussed above, dispersing larvae characteristically arrive at potential settling sites in a highly patchy manner. Such systems are said to be strongly affected by recruitment variation, where recruitment refers to the process of a larva settling at a particular patch (Kritzer and Sale, 2006). Differences in the spatio-temporal patterns of recruitment have the potential to contribute to species coexistence. In this case, the environmental advantage that a species has in a particular patch is proportional to its arrival rate there.

There is a very simple graphical technique for understanding the effects of variation in recruitment rates in space, which serves to illustrate how spatial environmental variation, and its interaction with population density, may have important effects. Figure 9 assumes a community with two competing species and plots the proportion of new inputs to a local community as a function of the local environment and the regional abundance of the species. The two solid curves correspond to two environment types. The x-axis is the proportion, p_t , of species 1 in the system as a whole. The y-axis is the proportion, s_{t+1} , of the available space at the site taken by new settlers of species 1 during the time interval from t to $t+1$. The upper curve refers to patches favoring settlement of species 1, whereas the lower curve is for patches favoring settlement of species 2. The difference between the different sorts of patch is in the relative arrival rates of larvae of the two species: more of species 1 arrive at upper-curve sites, and more of species 2 arrive at lower-curve sites. The species compete for available space at a site, which is assumed limiting and thus

Figure 9 Local and regional settling fractions (proportion species 1) as a function of regional fractional abundance for a marine space-holding community with two species. Upper solid curve: local environment favoring species 1, lower solid curve: local environment favoring species 2, and wavy dashed curve: regional settling fraction with 2/3 of patches favoring species 1. The regional equilibrium is the intersection of the wavy dashed curve with the diagonal dashed line.

filled by the larvae arriving each year. Note that if there were only one sort of patch in the system, eventually one species would eliminate the other, because it would have higher settlement success everywhere, and would increase in abundance relative to the other species. For example, if all sites favored species 1 (upper curve), then the fraction of species 1 settling would always be higher than p_t . It follows that species 1 would steadily increase until it had taken over altogether, assuming that settled individuals of both species have the same mortality rates (a simple adjustment, however, extends this idea to different mortality rates) (Chesson, 2000).

In Figure 9 it is assumed that two thirds of patches favor species 1, and one third favor species 2. This means that the average proportion of settlers, s_{t+1} , that belong to species 1 regionally is $(2/3)$ upper solid curve + $(1/3)$ lower solid curve, which is given by the points dividing the vertical lines between the two solid curves in the ratio 1:2. The dynamics of regional settlement are then given by the wavy line between the two curves. Depending on the actual adult mortality rates of settled organisms, the regional proportion, p_{t+1} , of species 1 at time $t+1$ will lie somewhere between p_t and the regional s_{t+1} . Thus, the point where the wavy line crosses the diagonal is the equilibrium point for the system, i.e., the point where p_t does not change over time. It is a stable equilibrium point too: if the value of p_t is less than the equilibrium, then the regional s_{t+1} is always greater than p_t and so species 1 increases in relative abundance ($p_{t+1} > p_t$). However, if p_t is above the equilibrium, the regional s_{t+1} is less than p_t and so species 1 decreases in the system. Hence, whenever the system is away from equilibrium, it moves back towards equilibrium over time.

These results apply whether a patch continues to favor the same species forever, or favors different species at different times, for example, if environmental conditions responsible for larval transport change over time. These results do have to be modified, however, if instead all patches favor a particular species at a particular time, but the favored species changes over time, for example, if the environmental conditions applicable to a particular year favor one species over the other everywhere. In that case, the environment is varying purely temporally. The way temporal variation affects the dynamics of an organism is greatly influenced by life-history parameters, such as the adult death rate because this determines how long past effects of fluctuations in settlement are reflected by the age-structure of the population. A low adult death rate means that a species can persist over periods when it is at a competitive disadvantage without its population density declining too greatly. It follows that the ability of species to coexist as a result of temporal variation varies inversely with the adult death rates (Chesson, 2003). With irregular temporal fluctuations, the system does not have a traditional equilibrium, but nevertheless can still exhibit stable fluctuations about a mean value as depicted in Figure 10.

Temporal variation is an important feature of many systems, and a mechanism like that described here, termed as the storage effect, has been suggested for coexistence in tropical trees where highly variable fruit production occurs, in annual plants where seed germination may vary greatly between years but seeds survive over unfavorable times in the soil seed bank, and also in annual zooplankton in lakes where a resting egg bank takes the place of the seed bank (Chesson, 2003).

Figure 10 Fluctuations in abundance (proportion of sites held) for three competing space-holding species experiencing independent temporal fluctuations in recruitment rates (thick wiggly curves) and constant recruitment rates (thin smooth curves).

Lessons from Metapopulation Theory

Conservation

Few populations in nature exist without important spatial structure. Although there is debate over how often that structure conforms to a strict metapopulation, the metapopulation concept is important in conservation biology because habitat fragmentation creates distinct local populations even if they could not be defined before human interference. There is no question that the inhabitants of small isolated habitat fragments are at risk of local extinction. Although a collection of such habitat fragments may genuinely be thought of as a metapopulation, recolonization rates may be so low that each local population will go extinct before any are recolonized. Metapopulation theory emphasizes the need, at a very minimum, for the recolonization rates c to exceed the extinction rates ε . Habitat destruction not only puts populations at risk by reducing their total size and spatial extent, but by altering the connectedness of the remaining habitat, it reduces the value of this remaining habitat.

Metapopulation theory also says that even uniform reduction in recolonization rates with habitat destruction may have different impacts on different species in the system. The system therefore may change in character with habitat destruction even under conditions that on the surface may not appear biased in favor of one species or another. Such effects have the potential to disrupt the functioning of ecosystems. This is a general message not specific to strict metapopulations. The metapopulation perspective also teaches that not only inhabited habitat is a suitable habitat. A species may be only temporally absent or in low abundance in an area, and that habitat may in fact be playing an important role in the system. Empty habitat must be judged in terms of its potential role as part of a larger connected system. Short-term environmental fluctuations may play a role in changing the suitability of habitat patches. Patches that are unsuitable at present may have the potential to become suitable in the future. With the prospect of global climate change, the maintenance of a diversity of patch types, and a landscape structure

suitable for migration of organisms between patches, are of major importance in reducing the loss of biodiversity.

Nonequilibrium Dynamics

The metapopulation perspective highlights the role of non-equilibrium conditions in space, i.e., situations in which local populations do not remain near an equilibrium population size. Simple predator–prey and host–parasitoid models commonly do not have both species coexisting stably in isolated patches. Nonequilibrium locally in space, that occurs asynchronously in different patches, has an essential role in stabilizing the spatial extensions of these models. Similarly, in successional mosaic systems, perturbation from equilibrium (domination by one species), locally in space, is critical to maintenance of the system. Such essential roles for non-equilibrium conditions have sometimes been taken as that the system is particularly robust to perturbations, including habitat degradation, by human activities. There is no reason to expect this to be true. Indeed, the message here is that equilibrium occurs on the larger spatial or temporal scales. Interfering with the system through habitat destruction, alteration in the disturbance frequency, alteration in mean environmental states, and alteration of the variance in environmental states all have major consequences, and are therefore of serious concern even though on small scales the system may not be at an equilibrium.

Population Regulation

These metapopulation and structured population perspectives also have the potential to resolve the long-standing debate over the relative importance of environmental fluctuations versus density-dependent interactions within and between species. Andrewartha and Birch were the first to clearly articulate metapopulation structure as an important feature of nature (Hanski, 1999), yet because of the prominent role of stochastic factors (factors with random elements), such as extinction and colonization, they believed that density dependence was of minor importance. The quantitative analysis here shows that far from being of minor importance, density dependence within local populations has a major role in shaping the nature of population dynamics at the metapopulation or regional scale. Density-dependent processes lead to nonlinear dynamical relationships, and we have seen how such relationships interact with fluctuations in time and space to give outcomes at larger temporal and spatial scales that are not predictable on the basis of the separate effects of these factors.

Glossary

Autocorrelation Densities from adjacent samples are likely to be more similar than are ones far apart.

Compound Poisson distribution A family of probability distributions of numbers per area where some areas have a higher expected density than others.

Poisson distribution The probability distribution of numbers per area if the organisms are distributed completely at random in space.

Measuring Population Density

Generally (although inevitably not exclusively), population density of a species of organism is measured either as a feature of a natural (or manipulated) system that responds to the environment or as a predictor (natural or manipulated) or causal agent of some response of the ecosystem.

As a Response Variable

Population density is often used as a simple relative measure of how an organism responds to local conditions. If conditions are not good for the species, the density will be low (organisms will have died or moved out of the sampled area), whereas if conditions are good the density will be high (organisms will have reproduced and/or immigrated into the area). In this way, changes in density can provide insight into the natural history of the preferences and tolerances of individuals of the species. Of course, if the species is regulated by density-dependent processes (e.g., mortality or emigration) then the relationship of density with the attractiveness of the environment can be obscured. Even though the environment changes in a positive way, there may be no increase in density.

Sometimes, density can be used as an explicit proxy for population size, which of course is what many ecologists want to know about. This is particularly true in applied ecology (e.g., conservation and fisheries science). Unfortunately, the link between population density and population size is not always direct (Gaston and McArdle, 1994). Therefore, definitions of rarity that use either population density or species range are likely to be misleading compared with a definition that uses the product of the two.

The main problem lies in defining the area to be sampled. If it includes the entire population of interest, then the density multiplied by the area gives total population size. However, if the area does not include the whole population then this simple calculation does not work. However, it will perhaps give a relative measure of the population so that changes in the population size will be reflected in changes in the density. Unfortunately, density-dependent processes can weaken this link. If, as the population increased in size, the population was unable to expand the area it inhabited, then the density would increase in proportion to the size. However, if the population

was able (or driven by density-dependent migration) to expand its range, then the density could remain constant whereas the population grew. Since range expansion appears to be common, density should only be used as a proxy for population size when the range is constrained, as on islands. In most studies, therefore, density simply gives the number of organisms present in some defined study area. Even today when habitat is increasingly fragmented, this will seldom correspond to a biological population.

As a Causal Agent

In many studies, changes in density are seen as causing changes in the population of the same or other species. For example, many experiments are performed each year in which the density of organisms is manipulated (or simply observed) to investigate the response of individuals in the same species (e.g., intraspecific competition) or other species (e.g., predation or interspecific competition). In such studies, the biological effect of density is generally determined by the number of direct or indirect interactions between individuals (of the same or different species). Density in this case is often acting as a proxy for the number or probability of interactions. There are problems associated with this use of density. In particular, the area has to be defined carefully. If the area for which the density is being estimated includes habitat unsuitable to the study species, then the zeros measured from such sites are not due to sampling error (sampling zeros) but reflect a genuine inability of the species to live there (structural zeros). Including structural zeros in the density estimate would lead to an underestimation of the density that individuals of the same species actually experience. Of course, if it is the response of other species that is of interest, then these areas of habitat may be relevant (other areas may not). Again, the purpose for which the density is to be used determines how one defines the area over which it is to be measured.

There are additional problems. It is well known that even if one defines the extent of the study area, estimating the number of organisms can be difficult. Perhaps less well appreciated is that natural surfaces can be generally considered as fractal (or at least approximately so). The effective area of a given area of the earth's surface experienced by an elephant is considerably less than that experienced by a mite. The area used to calculate the density of the organism is nearly always

anthropocentrically biased. The more similar the organism is to humans with regard to size and habit, the more accurate the estimate of effective area is likely to be, and therefore the more relevant the estimate of density.

Of course, a simple estimate of density can still be used as a relative measure of the effective density. However, it must be remembered that organisms are seldom (if ever) uniformly distributed over a study site. Typically, some parts of the site have a high density and others a low density. If most of the organisms are located in one small part of the site, the average density for the site will reveal little about the density most experienced. The marked nonlinearity of most ecological dynamics means that inferences based on the average density are unlikely to be particularly relevant. The situation is similar though more complex when one is interested in the density of one species experienced by another (e.g., in predation or interspecific competition studies).

Population density is therefore nearly always used as an approximate proxy for the real abundance measure of interest. The degree to which it can be regarded as relevant in a particular study depends to a large extent on issues of scale.

Spatial Patterns

Within a species' range, we can expect the density to vary with the habitat from high (optimal) to low (suboptimal). The effect of this on the ground depends on the scale at which one is sampling. For example, at the largest scale it has often been noted that the density of a species tends to be highest in the core of its range and lowest at the periphery. However, much local variation can still exist within the species range at a number of scales down to that of the individual organism (spatial pattern often depends on spatial scale). Similarly, the range and regions of optimal conditions may be temporally variable. For small animals such as insects, the vagaries of wind and weather can lead to shortlived increases in different geographic regions at different times (Figure 1). Other species (e.g., habitat specialists) tend to be far more predictable. Of course, temporal stability can be dependent on the scale: The spatial pattern might be relatively stable at one scale (e.g., geographic region) but not at another (e.g., locally within habitat patches).

It is worth noting that although we may often refer to the density as patchy, the pattern of variation is often more continuous. The pattern is better shown with contour maps rather than with a tiling or mosaic. The edges of the so-called patches may not be real discontinuities but rather areas of lower density. The density within the patches may not be constant. Therefore, although we may often talk in terms of patches, we must think in terms of contours. Of course, thinking in terms of patches is an implicit acknowledgment that the presence/absence data are often more reliable and easily interpreted than abundance or density data. This is because the organism counts produced by most sampling programs are subject to considerable statistical sampling error.

Statistical Patterns in Spatial Variation

One of the most common ways of investigating population density is to count organisms in small representative portions

(e.g., quadrats) of a larger study area. Then, one estimates the mean density or total numbers in the study site. One can also deduce many characteristics by examining the frequency distribution of the counts per sampling unit.

The most obvious feature of real data is that the frequency distribution of these counts is long tailed and heavily skewed (Figure 2). Low densities are common, but very high values sometimes occur. As a general rule, a relatively small number of sampling units contain most of the organisms, and many of the sample units are empty. This indicates a fundamental difference between total number of organisms and the typical density experienced by members of another species (e.g., a predator or competitor) or the typical density experienced by members of the population.

Thus, the total number of animals in the whole area is estimated by the arithmetic mean $\times$ total area. However, the typical number of animals found in a quadrat, i.e., the density of the species most commonly experienced by other species (e.g., predators) searching at the same scale as the quadrats under study, is given by the median number per quadrat. This is approximated by the geometric mean, $\text{antilog}(\text{mean}(\log(\text{count})))$, or more commonly by the pseudogeometric mean, $\text{antilog}(\text{mean}(\log(\text{count} + 1)))$. The number 1 is added to each count to overcome problems with zeros. However, the density most commonly experienced by members of the target species is neither of these. Since most of the animals are in a few quadrats, most experience very high densities. Thus, the best estimate of the effective conspecific density, the average density experienced by a member of the population at the spatial scale of the quadrat, is very different. Simply, there are N_i animals in the i th quadrat that experienced a density of N_i , and the density experienced by the average animal is therefore given by $\sum N_i^2 / \sum N_i$, which gives a density that is very different from the other two average densities.

Statistically, there are many distributional models that could fit these kinds of quadrat count data. The most commonly used are members of the compound Poisson family (e.g., negative binomial and Poisson log-normal). That these long-tailed distributions fit in no way suggests that the mathematical processes that generate them have anything to do with the biological processes that generated the numbers. However, there are a few interesting ideas that can be derived from these distributions that may have biological relevance in some situations, and which when combined provide some understanding of one of the few ecological laws discovered to date (see Taylor's Power Law).

The simplest way of viewing these models suggests that the expected density of organisms at any point in space derives from some long-tailed continuous distribution (a gamma for the negative binomial, and a log-normal for the Poisson log-normal), but that the number actually recorded is from a Poisson with that expected value. There are many ways of parameterizing these distributions, but perhaps the most useful is with the mean (m) and shape parameter (k). The shape parameter defines the relationship between the variance and the mean. The relationship is often displayed as: $\sigma^2 = \mu + (1/k)\mu^2$ indicating that the variance of the counts increases approximately as the square of the mean, with the rate determined by the shape parameter. A small $1/k$ leads to small variances for a given mean, whereas a large $1/k$ leads to large

Figure 1 Maps showing the variability of regional relative density in five British moth species with very different dynamics: (a) *Xanthorhoe fluctuata* (golden carpet moth) is a widespread species, numerically fairly stable but with mobile holes in its distribution, (b) *Cerapterix graminis* (antler moth) has a distribution limited by its host plants (fine upland grasses), but within these limits the distribution of density is constantly changing, (c) *Euxoa nigricans* (golden dart moth) has a spotted distribution that is spatially and temporally chaotic (consider how difficult it is to define the range of species such as this), (d) *Spilosoma lutea* (buff ermine moth) has a numerically very stable population with an unstable northern limit, and (e) *Callimorpha jacobea* (cinnabar moth) is highly concentrated in suitable areas but has a highly mobile distribution. Reproduced from Taylor RAJ and Taylor LR (1979) Population dynamics. In: Anderson RM, Turner BD, and Taylor LR (eds.) *The 20th Symposium of the British Ecological Society*, pp. 1–27. Oxford: Blackwell, with permission from Wiley.

Figure 2 Frequency distribution of density (per 0.25 m²) of the New Zealand cockle (*Austrovenus stutchburyi*). A compound Poisson (negative binomial) distribution is fitted. Note the extremely crowded quadrats; more than 50% of the animals are in quadrats with densities of more than 30 per 0.25 m², although the mean density is only 16.9 (median = 11). The estimated shape parameter k of the negative binomial is 0.61.

variances. Thus, large $1/k$ values suggest high aggregation (some quadrats containing high numbers of organisms and some quadrats containing low numbers), and low $1/k$ implies low aggregation. ($1/k=0$ suggests a Poisson distribution for organisms whose dispersion is indistinguishable from random.) Therefore, $1/k$ and related statistics are commonly used as the aggregation indices. If the statistical basis of the compound Poisson was in fact correct (i.e., expected density at a point varying spatially, and the number actually collected a Poisson variable), then $1/k$ separates the Poisson sampling error from the underlying distribution of expected density. Indeed, it is the coefficient of variation squared of the underlying distribution of expected density, i.e., the ratio of the variance of the gamma or log-normal with the squared mean:

$$\frac{1}{k} = \frac{\sigma_x^2 - \mu}{\mu^2}$$

Compound Poisson distributions have a biologically relevant property. If a population of organisms is distributed in an aggregated fashion and if some of them randomly die, the mean density changes but the shape or aggregation parameter of a compound Poisson distribution does not. This is of course as it should be: Random mortality leaves the degree of aggregation unchanged. Therefore, if the compound Poisson family of distributions is appropriate, the basic relationship between mean and variance of animal densities (counts) should be $\sigma^2 = \mu + (1/k)\mu^2$ if mortality is operating randomly in space. Of course, there is no need for this to be true (indeed, it might be considered unlikely). Real data might be expected to show a general relationship similar to this, but the degree of aggregation will change with the mean density (possibly due to the density-dependent processes). This is the case for virtually all sets of field data. Therefore, the compound Poisson models are not necessarily always appropriate, but they often fit the available data.

In recent years other distributions have been applied. For example, the Zero-inflated Poisson distribution. The model

here again assumes two separate processes: some sample units are from places where the organism is unlikely to be found (modeled by a simple Binomial distribution), others are from places where it can be found at a constant expected density, the number actually collected will be a random count from a Poisson distribution. Apart from the constant expected density in areas where the animal can be found, this version of a compound Poisson (a Binomial and a Poisson) is eminently plausible to ecologists, particularly when the area to be sampled is large enough to include areas the organisms cannot inhabit. It also acknowledges the important distinction between structural zeros (the organisms do not live here) and sampling zeros (they can live here, your sample, by chance, failed to catch any). It is generally more frequent to use an extension of this distribution, the Zero-inflated Negative Binomial, which accepts that in those areas where the organisms can exist they are unlikely to have a uniform expected density. Interestingly, both these distributions also have variance–mean relationships of $\sigma^2 = \mu + c\mu^2$. It is worth pointing out that due to the extreme flexibility of the negative binomial and Poisson log-normal it is usually extremely difficult to convincingly demonstrate, which of the four distributions described above is most appropriate for general use (though the Zero-inflated Poisson is generally the least adequate). Generally they all fit pretty well.

Taylor's Power Law

One of the few ecological laws that have some universality was discovered in 1961 by L.R. Taylor. He worked with populations that had been sampled at many sites on many occasions. He showed that the variance of the densities over the sites on an occasion when plotted against the mean density over the sites on that occasion resulted in a very tight power curve. A plot of log (variance) against log(mean) gave a generally straight line (Taylor's power plot (TPP)). This implies that the formula is $\sigma^2 = \alpha\mu^\beta$ (Taylor's power law). As might be expected from the compound Poisson model, the slope of this line is often close to 2.

This plot and the formula are not just applicable to organism abundances. They are commonly used by statisticians searching for transformations to remove the variance–mean relationship and therefore variance heterogeneity, a problem for many traditional methods of statistical inference. They try to find a transformation that gives a slope of zero to the log(variance)–log(mean) relationship.

Real data are seldom quite so obligingly simple as Taylor's original model implies. Indeed, the dominant pattern is linear in the log–log plot but curved at low densities. Alternative formulae have been suggested to accommodate this. The modified compound Poisson (or Nelder) model $\sigma^2 = \mu + \alpha\mu^\beta$ generally performs well, as does a split straight line, although the threshold that the latter implies seems unlikely to some biologists. Since some populations are demonstrably not Poisson even at the lowest densities, alternatives such as $\sigma^2 = \gamma\mu + \alpha\mu^\beta$ and $\sigma^2 = \gamma + \mu + \alpha\mu^\beta$ have also been used.

Although there may be a variety of models, the basic pattern in the data is clear, but the interpretation is not. In all these models, the parameters α and β have a simple statistical interpretation, but what they imply about the population

dynamics is less clear. The parameter α clearly represents the variance (and therefore the level of aggregation) when the mean density is 1. In the modified compound Poisson (or Nelder) model it represents the value of $1/k$ when the mean is 1. If $\beta=2$, then this suggests that the level of aggregation is constant at α at all densities. Thus, contrary to much that has been written about the use of the TPP, it is α that tells us about aggregation and not β . The slope of the relationship (β) indicates how rapidly aggregation changes with the mean and not the level of aggregation. To make this clear, we can rewrite the modified compound Poisson model as $1/k = \sigma^2 - \mu/\mu^2 = \alpha\mu\beta^{-2}$. Aggregation is therefore related to density by a power relationship (i.e., a linear relationship in a log-log plot). Thus, $\beta - 2$ indicates how aggregation varies with the mean. Of course, if $\beta \approx 2$ the level of aggregation arguably does not change with density. If $\beta < 2$ then aggregation decreases as density increases. This is consistent with density-dependent migration out of higher concentrations into lower ones, evening out density variation as the overall mean density increases. If $\beta > 2$ then the organisms are becoming more concentrated – for example, if population growth were restricted to areas of higher density with no diffusion. Of course, it would be very unwise to link any value of α or β to a particular dynamic process. One reason is that α and β depend on the particular context (habitat, sampling method and scale, and even the age structure of the population) of the study and not, as suggested by Taylor, on a characteristic slope β for a species and an intercept α depending on the sampling situation. This makes it difficult to interpret TPPs with any confidence. However, with the spatial variance $\times$ multiple times data sets originally studied by Taylor, the patterns of variation implied by β can help us understand the biology of the species at least for the site and scale studied.

Interpretation is much more difficult if the TPP is generated by a spatial variance $\times$ multiple sites sampling scheme. Here, the variance is over samples (e.g., quadrats) taken within a site, but each point on the graph is given by a different site. Since habitat is likely to vary over sites, we are likely to be looking mainly at patterns of habitat variation and utilization. A $\beta > 2$ might imply that sites with higher means had greater local concentrations of resources than sites with lower means. A $\beta < 2$ might suggest that where the resources were abundant, rather than being locally concentrated they were distributed more uniformly. Of course, the concept of resources is a broad one that includes predator- or competitor-free space and other dynamic features of the environment.

Within-Species Occupancy-Abundance Patterns

In recent years a number of workers have noted that there is a clear relation between the abundance of a species and the number of sampling units in which it is recorded. A number of models have been suggested but they are mainly variants on $p = 1 - (\mu/k)^{-k}$, where p is the probability of a sample unit being occupied, i.e., having an individual recorded on that sampling occasion, and k is the shape, “aggregation,” parameter of the negative binomial distribution. This model is simply the proportion of nonempty samples predicted by the negative binomial with those parameters. It has been

combined with Taylor’s power law to provide a better fit to the data (since k varies with the mean μ if the slope β of the TPP is not 2) – Gaston *et al.* (2006). An alternative approach to describing the relationship has been tried using Zero-inflated Negative Binomial models, but there is little evidence that either of the models fit the data better than the other. Both seem to do adequately.

Density-Biomass Thinning Laws

In this article, population density has been defined as the number of organisms per unit area. However, there is no reason why density should not be measured using other properties of the population. Probably the most common alternative to abundance is biomass. It should therefore not be surprising that there is a relationship between the two measures of density. However, nonbiologists might be surprised by the relationship that seems to exist in plants.

Plants: – 3/2 Thinning Rule (Yoda’s Law)

In 1963, Yoda and coworkers noted that if a cohort of plants were monitored over the course of a growth season, there was a clear negative relationship between the biomass and numerical density as the plants “selfthinned.” This relationship seems to be well modeled by a power relationship:

$$B = cN^{-b}$$

where B is the biomass density, N is the density, and c and b are constants. The value of $-b$ has generally been thought to be between -0.3 and -0.8 with an ideal value at -0.5 . It is generally assumed to be the result of density-dependent mortality and allometric patterns of growth interacting with the way in which trees pack together in the canopy. It is called the $-3/2$ thinning rule because it is commonly formulated in terms of w , the biomass per individual, as

$$w = cN^{-a}$$

where $a = b - 1$. The exponent is now between -1.3 and -1.8 with an ideal value of -1.5 .

In recent years, its generality has come into question. There does seem to be a generally negative relationship between density and biomass in most investigated species, but there is little evidence that there is any ideal value of a , let alone one of -1.5 .

Animals: – 4/3 Thinning Law

In contrast to the empirical origin of the plants’ thinning law, zoologists derived an analogous rule for animals from theory. The postulated relationship is again a power function $w = cN^a$, where $-a = -4/3$ rather than $-3/2$ as in plants. To date, it has been most convincingly shown in salmonid fish but even there the exponent seems to be spatially variable.

Determinants of Spatial Density Variation

Although the existence of spatial variation in the population density of a species is almost trivially selfevident, the processes that can produce it are many and varied. This reinforces the

problems of inferring process from pattern. The mere existence of spatial variation at any given scale is seldom enough to suggest the processes that generated it. There are three main classes of processes that generate spatial variation in density.

External Forcing

The most obvious (and at many scales probably the most common) cause of spatial variability in population density is variation in the quality of the available habitat. If the environment varies spatially at any scale, so will the density of many species. A patchy environment usually produces a patchy distribution of organisms. Of course, some species will be affected more than others. There is enormous variation in the tolerance of organisms to variation in environmental factors.

Another external influence (which might be viewed as a special case of environmental variation) might be the distribution or spatial response of predators or competitors. Predator- or competitor-free space can be as significant a resource as food or space with suitable environmental conditions. Other things being equal, higher density can be expected in such areas.

Lifestyle Characteristics

Of course, interactions among conspecifics can also lead to spatial variation in density. Social aggregations of many kinds are common in animals and at some scales can lead to variation in density that is independent of the environmental conditions. Conversely, random variation in density at local scales can be reduced by spacing behaviors (such as territoriality).

Some of the possible conspecific interactions are not strictly social. Many species modify the local environment, which makes it more attractive to recruits (e.g., larval settlement). This can also result in the formation of aggregations.

Other biological processes result in strong aggregations. Individuals from some species have little choice regarding where they will live (e.g., most plants). Those that start life close to their parent (e.g., many forms of vegetative reproduction, nondispersing seeds, and colonial animals) will stay there. Aggregations will often be the result.

Population Dynamics

Perhaps one of the most topical areas of research concerns the possibility that spatial patterns of density variation could be the result of intrinsic dynamic processes – an emergent property of the dynamic system of which the population is a part. Arguments are often taken from complexity or chaos theory and often refer to the behavior of cellular automata models (such as the Game of Life referred to in most popular texts on complexity and chaos theory).

In fact, as one might expect, the tendency of spatially distributed dynamic systems to produce a spatial pattern is related to a very simple property of the system, which in ecology has a simple biological interpretation. Phipps (1992) postulated that spatial pattern will only be produced in cellular automata models if areas neighboring high-density sites are

more likely to achieve high density than other areas. He called this the neighborhood coherence principle. In ecology, this predicts that only species that attract conspecifics either by recruitment (e.g., vegetative growth or limited dispersal from place of birth) or by movement (e.g., flocking) or that somehow reduce the death rate in areas near high densities are likely to show intrinsically generated spatial patterning that is independent of environmental forces. All the sophisticated theory results in a trivial prediction that social and other aggregative behaviors are the main reason why spatial pattern emerges in populations for which the environmental factors have little influence. Generally, the more important question is the following: Given that the biology of the animal predisposes it to aggregation, why is it not more obvious? Density-dependent forces such as predation and emigration that tend to reduce high densities will tend to prevent major concentrations. It is the balance of these ecological forces that produces the observed patterns. This is not to say that there may not be other system dynamics that can produce spatial patterning, but they will almost certainly be similarly spatially nonrandom in their action or somehow be relatable to the forcing processes described previously (see External Forcing) and, above all, they will be biologically obvious. There is nothing mysterious about the action of nonlinear dynamics in producing spatial patterns. It depends on the properties of the system and in a biological context seems generally to agree with common sense.

Consequences of Spatial Density Variation

Population Dynamic Consequences

The existence of spatial variation in population density implies consequences at both the individual and the population levels (and other scales in between). The most obvious is that the state of the individual is frequently influenced directly and indirectly by the surrounding density of conspecifics (intraspecific density-dependent processes). The direct effects may include behavioral changes (e.g., increased propensity for emigration), physiological changes (e.g., increased stress hormones and reduced or enhanced sexual activity), or even morphological changes (e.g., the social phase of locusts). It must be appreciated, however, that the density perceived by an individual will seldom be that measured by researchers. Again, the issue of scale is crucial. Measuring density averages counts over areas and reduces variation at smaller scales. These may, however, be the scales at which the individual's perception operates. Local high densities determine the perceived density per individual and the resulting consequences.

Similarly, the indirect consequences of local high density can be very different than expected if one simply examines the average density at a larger scale. The impact of predators, parasites, and pathogens can be very different if the organisms are concentrated rather than uniformly distributed. Spatial variation in density can be as important as differences in overall average density.

These considerations have led to an increasing appreciation that population dynamic models should be spatially explicit. A move in this direction started with optimal foraging models,

but recently entire populations have been modeled in this way. One class of such models is those that describe metapopulations. A metapopulation is a population of subpopulations. Although this is usually an oversimplified spatial pattern – all organisms are in discrete, fixed clusters or in transit between them – the behaviors are quite different from those in a simple uniform population model. Rate constants (e.g., birth or death rates) averaged over a spatially distributed population will seldom adequately reproduce the behavior of a population. It is worth noting that models that use discrete partitions of space do not behave in the same way as those based on continuous space (i.e., on differential calculus). Therefore, although ecologists are currently attempting to produce more realistic models by incorporating space, the way it is incorporated may influence the conclusions.

Genetic/Evolutionary Consequences

Although the population dynamic effects of density variation may be important at a variety of scales, the evolutionary consequences have been considered only at larger scales: a subpopulation of organisms becomes spatially isolated from the rest and allopatric speciation may then occur. Work by D.S. Wilson on multilevel selection theory has incorporated the spatial organization of organisms into groups at different scales to expand the range of evolutionary forces.

One genetic consequence of low density and high aggregation in less mobile organisms is the possibility of genetic drift and inbreeding. Such populations are possibly more vulnerable to disease and can show depression of reproduction rates if the aggregations are stable and isolated.

Temporal Patterns in Density

When population density is plotted against time, a logarithmic scale is often used because populations can fluctuate so widely, over many orders of magnitude, that the arithmetic scale is inadequate. Locusts are an obvious example. However, for many species the magnitude of the fluctuations depends on the temporal and spatial scale over which the density was determined. For example, insect species with a single synchronized generation per year will fluctuate enormously within the year – huge numbers of eggs and first-instar larvae decline throughout the year to much smaller numbers of adults – but might not fluctuate much between years. If one averaged or totalled density over the year, much of the variation would be smoothed out. Similarly, sampling at the same time each year would also not provide information about within-year variability. The spatial scale over which the density is averaged is also crucial. Variation in the density of starlings through time will appear very different when measured at the scale of the bird table, the garden, or the suburb.

Shape of Distribution

Although the nature of the distribution of organism counts sampled in space is well known, far less effort has gone into characterizing the distribution of counts in time. Part of the

reason, of course, is the difficulty in obtaining long time series of suitable data. Also, often the data are not independent; rather, they are autocorrelated: The value at one time will be more similar to recent values than those from later times. This makes characterizing the distribution difficult. At this stage all that can be sensibly stated is that, like the spatial distributions, they are discrete and long tailed, and the members of the compound Poisson family could be used as an initial approximation. However, the autocorrelation often leads to multimodality in real, short time series.

Red-Shifted Variance

One observed characteristic of such time series of density data is that, generally, the variability (measured, e.g., as $SD(\log(N))$) increases with the length of the series. There are at least three phenomena, which can produce this effect, and they are not mutually exclusive: (1) *Long-term trends*: If density is consistently increasing or decreasing over time (as commonly occurs due to human impact and climate change), then its variance will naturally increase as long as the trend continues. (2) *Internally generated autocorrelation in the series*: autocorrelation (or serial correlation) is present when the density at the next sample occasion is similar to the current value, perhaps because some of the same organisms are still living (interval between samples < generation time) or because the number living at the next time period depends on the current breeding population. In this situation, short time series cannot vary widely, but as the series becomes longer the variance gradually increases to some asymptotic level. This is of course particularly common with long-lived species that, naturally, we sample at a frequency convenient to us but not necessarily relevant to the species. (3) *Externally forced autocorrelation*: If the physical environment fluctuated in an autocorrelated fashion then the population's density might vary in response. Such autocorrelated time series are characteristic of "red-shifted" spectra of environmental variables (characteristic of climatic factors). It may be worth mentioning that Power law distributions that describe scale-free properties of certain systems have, for most realistic values of their parameters, variances that increase with sample size.

Taylor's Power Law

If time series of densities are produced for many sites, then a plot of the variance over time against the mean over time for the sites will provide a close relationship, as occurs for spatial variances and means. Essentially the same models describe this relationship as those used for the spatial TPP. Temporal variance increases with the mean as does spatial variance. Again, the slope is usually approximately 2. The intercept α measures the variability when the average density at a site is 1, and therefore it describes a sort of baseline temporal variability at this spatial and temporal scales. The slope β describes how this variance changes for sites that have higher or lower densities. A slope of 2 suggests that there is essentially no change in variability at higher densities. Values higher than 2 indicate that the species is more variable at denser sites. This is a behavior characteristic of species subject to local

explosions in numbers at certain sites. A good site is sometimes good and sometimes bad. A bad site is always bad. A slope of less than 2 means that sites with generally high densities tend to be less variable than poor sites. This is consistent with density dependence, although other habitat-driven, or demographic stochasticity explanations are possible. Slopes of more than 2 appear to be relatively rare; less than 2, common.

Determinants of Temporal Density Variation

Although the processes that can produce temporal variability in density are similar to those that produce spatial variability, they are not identical. The effects of choices of scale tend to be greater. However, the same three classes of factors are discussed.

External Forces

Fluctuations in the environment will drive temporal variability of density in many species. Invertebrates in particular are at the mercy of the elements, although vertebrates are demonstrably not immune. The extreme winter of 1962 and 1963 in the British Isles resulted in a marked decrease in the densities of many bird species that took years to recover. The densities of many marine organisms are driven by El Niño-like phenomena (as are many terrestrial organisms). The threshold-like effects of many environmental variables can lead to large fluctuations in organism densities. For example, a species may not breed until the temperature is above some value (which may only happen every few years) or unless rain falls (especially in desert species).

Of course, the consequences for a species of such fluctuations in the physical environment may be indirect. Food, competitors, disease, and predation may also be driven variables, in many cases amplifying or extending the direct effects. Clearly, an organism's lifestyle (food/nutrient requirements, vulnerability to disease or predation, etc.) can also influence its susceptibility to such forces.

Life History Characteristics

Life history characteristics, such as synchronized generations or life stages (perhaps dormant) that are not available for sampling (e.g., the seed bank or the nymphs of the 21-year cicada), can lead to apparently major changes in density. Arguably, the variation is the result of a particular definition of density. Whether such a definition is useful will depend on the question under investigation.

Some species have reproductive strategies that amplify fluctuations in density. Physiological and/or morphological changes (usually triggered by habitat characteristics) can lead to dramatic increases in population growth, for example, the shift from sexual to asexual reproduction when conditions are good.

An organism's mobility (or its ability to disperse propagules) can also influence its temporal variability. If it has an aggregated, patchy, spatial distribution (e.g., metapopulation structure) the degree of connectedness between the parts of the population and the degree to which they fluctuate

independently can influence the extent of the variation of the whole population.

Population Dynamics

By definition, density-dependent processes should be major determinants of the degree of temporal variation. In fact, the extent to which such processes influence density is largely unknown. The problem is two-fold: (1) It has proved easier to study the apparent consequences rather than the process. That is, it is easier to show that changes in density over a period depend on densities prior to that period (the statistical detection of density dependence) than it is to show the ecological process that produced the relationship. However, there is little doubt that internal density-dependent processes cause many species to fluctuate less than they might otherwise. (2) The second process is more subtle. Complexity and chaos theory predict that certain combinations of high growth rate and strong density-dependent dynamics can lead to chaotic behavior in the resulting population densities. Since this can lead to apparently random fluctuating densities, it is difficult to separate the effects of density dependence from the results of external forces. Indeed, since these driving variables may be the result of chaotic processes (e.g., the weather or market forces), it is difficult to determine how such density-dependent effects can be distinguished without much more data about environmental factors than is generally available.

Consequences of Temporal Density Variation

Increased Probability of Extinction

The most widely discussed consequence of low density is the increased probability of extinction. Although it is difficult to demonstrate empirically, it seems obvious that a population whose size (not necessarily density) varies widely is more likely to go extinct (all things being equal) than a population whose size varies less. Once a population reaches low densities within a restricted spatial range, chance events can determine whether it has a future. If the numbers are sufficiently low a single death or failure to breed can lead to eventual extinction. It is worth reiterating that such stochastic extinctions are the result of low population sizes and not densities.

The probability of extinction can (occasionally) be influenced by low density *per se*. For example, regardless of the population size, at very low densities Allee effects may increase the chances of extinction. That is, if the density of a sexually reproducing species becomes so low as to affect the probability of locating a mate, then the population can start a slide to extinction from which it cannot escape. Of course, if the population responds by aggregating, then the distinction between local and regional density becomes crucial. Ultimately, it will be the fate of the aggregations, and therefore the total number of organisms, that determines the destiny of the population.

Cascade Effects

Of course, fluctuating densities of one species can have knock-on effects on other species. Patterns of density variation affect man's exploitation of the natural world. Outbreaks of pests or

periods of low fish density have economic consequences, and assessing the risk of such events is a lucrative job for well-paid consultants.

Such an anthropocentric view ignores the cascade of effects that are likely to propagate up and down the food chain, for example, the changes consequent on fluctuations in the density of kelp on the west coast of North America. Such effects are usually difficult to demonstrate unequivocally.

Evolutionary Consequences

Temporal variation in density can produce genetic bottlenecks with consequent loss of genetic variability. However, if the population rebounds rapidly the reduction in heterozygosity may be minimal.

Trans-specific Patterns

Comparing Densities across Species

It should be apparent that both the measure and the scale of a density must be appropriate for the processes or patterns of interest. In particular, the appropriate area might not be the same for different species. If perceived density of conspecifics is required, the appropriate area would probably depend on the movement patterns of individuals of the different species and would likely differ among species. If perceived density by a predator species is required, then the appropriate area would be defined for the predator and would likely be the same for most prey species. Since the biological relevance of a density depends on the processes being investigated, it is likely to vary between species. As a result, it is extremely difficult to interpret patterns of simple arithmetic density measured across species at some arbitrary scale. This is not to say that such patterns are not interesting (indeed they are sometimes tantalizingly so); however, interpreting the causes and consequences of these patterns will be more difficult because the measure and scale chosen will be to a greater or lesser extent irrelevant to the dynamics of most of the species.

In addition, many other factors complicate such trans-specific comparisons, for example, phylogenetic relatedness, which leads to statistical nonindependence and possible artifactual detection of pattern. Trans-specific patterns of population density must therefore not be taken at face value. Their meaning is seldom as simple as it appears.

Distribution of Density over Species

It has long been observed that organism abundances are approximately log-normally distributed over species, regardless of the size of the sample area. Preston (1962) suggested that this distribution, which he named the canonical log-normal, had a remarkably constant property, $(2(\text{SD log}_2)^{-0.5}) \approx 0.2$ (where SD log_2 is the standard deviation of the abundances after transforming using log base 2). This translates into a $\text{SD log}_{10} \approx 1$. In fact, subsequent work has demonstrated that nature is not so kind, but the SD log_{10} does appear reasonably consistent. An explanation based on the law of large numbers was given by R. May in 1975, who suggested that this phenomenon is inevitable when large numbers of species are

involved. Alternative models have been suggested, notably MacArthur's broken-stick model and the geometric log series. Although the log-normal model does not imply any ecological generating process, the other models usually suggest such a process. These (and other more complex niche partitioning models) often fit as well as a log-normal, but there is a danger that workers will infer a process from an adequate fit. The amount of information in a single sample frequency distribution is clearly not sufficient to distinguish between generating processes, especially given the difficulties of defining and comparing densities across species. It is worth noting that, like the Normal distribution, the Log-normal is a Stable distribution; meaning that it can be generated by a linear combination of an arbitrarily large number of other distributions. In the Log-normal case their values must be logged before combination. It can therefore be the result of the combination of a large number of multiplicative processes. No single process can be inferred from any data that could plausibly be log-normal.

Trans-species – 3/2 Thinning Law

The $-3/2$ thinning law has a trans-species extension (although the word thinning seems inappropriate). If we plot the maximum recorded density of species against their biomass density we should get a classic allometric power curve $w = cN^a$ with an exponent a of close to -0.5 . In 1998, Enquist *et al.* suggested that for the curve a is closer to -0.333 (a $-4/3$ thinning law like that suggested for the intraspecific relationship in animals). They suggest a theoretical support for this value.

The existence of a negative relationship between body size and density in animals has long been accepted. However, research suggests that there are two main shapes to the relationship on a log-log plot: linear negative (Figure 3(a)) and polygonal (Figure 3(b)). Other forms, usually nonlinear with a generally negative slope, have occasionally been suggested for other groups, but currently it is difficult to assess their generality.

The way in which the densities are estimated clearly influences the form of the relationship; in more than 500 studies investigated by Blackburn and Gaston (1997), the scale of the area considered (local vs. regional) was the most important factor. This reinforces the idea that until we know and understand the nature of the density that is being measured we cannot interpret any relationships observed with which it is involved.

The linear negative relationships had highly variable slopes and there was no tendency for them to cluster around -0.333 . Indeed, all the slopes (including manifestly polygonal ones) had a mean of -0.51 and a mode near -0.75 . Other workers have also found that an exponent of around -0.75 appears quite common, though by no means universal, and that no one theoretical explanation for the trend can be supported.

Evidence for the polygonal relationship appears to be declining as more systems are investigated.

Relationships with Other Traits

Breeding Systems

Characteristically low-density species (especially plants) rely less on outcrossing and sexual reproduction in general than do more common species.

Figure 3 Density–body size relationships showing the two main types. Note that despite having generally negative slopes, both have peak densities at intermediate body masses. This is a common phenomenon of unknown significance: (a) selection of mammals of the world (reproduced from Damuth (1987) as cited in Blackburn TM and Gaston KJ (1997) A critical assessment of the form of the interspecific relationship between abundance and body size in animals. *Journal of Animal Ecology* 66: 233–249) and (b) density (individuals per BBS route, $n=380$) for North American land birds (reproduced from Brown and Maurer (1987) as cited in Blackburn TM and Gaston KJ (1997) A critical assessment of the form of the interspecific relationship between abundance and body size in animals. *Journal of Animal Ecology* 66: 233–249), with permission from Wiley.

Reproductive Investment

It has been suggested that rare species (restricted range or low density) produce smaller numbers of propagules per unit time, although they often have longer life spans.

Dispersal Ability

In general, studies have shown that rare species (with restricted ranges and lower regional density) have poorer dispersal abilities than more common ones.

Homozygosity

As expected from theory, there is ample evidence that less dense species have lower genetic diversity than more common species.

Resource Usage

Since density, as previously noted, is often driven by environmental factors, it is not surprising that low-density

Figure 4 The relationship between local density ($\log_{10}$ territories ha^{-1}) and the proportion of sites occupied on farmland Common Bird Census plots in Britain in 1975. Reproduced from Gaston KJ, Blackburn TM, and Lawton JH (1997) Interspecific abundance–range size relationships: An appraisal of mechanisms. *Journal of Animal Ecology* 66: 579–601, with permission from British Ecological Society.

species are frequently associated with restricted or uncommon conditions and resources.

Trophic Status

One of the oldest ecological concepts, the ecological or Eltonian pyramid (Elton, 1927), predicts that the higher a species is in the food chain, the lower its density. There is ample evidence that this is usually true, but there are enough exceptions to remind us that few ecological rules have universal generality.

Latitude

For many years it has been suggested that density for a species tends to be higher in higher latitudes. (This surely has to be true for blood-sucking insects.) In part, this is a prediction of the density compensation hypothesis, which predicts that in communities of low diversity (e.g., islands) density will be higher. Although there is evidence to support this prediction for islands, the evidence for latitude is more equivocal.

Geographic Range

The relationship between abundance and range was first noted (publicly) by Darwin and has occupied many workers since. That it exists is not in doubt (Figure 4), but whether it implies anything of biological interest is debatable. The following is the central question: Does such a relationship imply anything about differences in life history between rare and common species? It is easy to show that in an environment that varies spatially in its attractiveness or ability to support species (as in the compound Poisson model described earlier) but in which all species have similar properties besides mean density (or at least whose properties are independent of their average density), there must be a positive relationship between density and the proportion of sites at which they are found. Such a relationship therefore does not imply anything about the life history or lifestyle of common compared to rare species (Kunin and Gaston, 1997).

To demonstrate that such differences do exist, it is necessary to compare the observed distribution of organisms with an appropriate null such as that discussed in the previous paragraph. This model is sometimes called the “sampling” or “artifact” model and has been shown to fit some data very well. However, it is not simply a sampling phenomenon, disappearing if a sufficient number of organisms have been collected or a sufficient number of areas are sampled. It is predicted by many population dynamic processes in which rate parameters (e.g., birth rate and death rate per individual) are independent of local density. Efforts to investigate the density–range relationship in the past have been made more difficult by only using the density at sites at which the species is actually present – local density (treating all zeros as structural and therefore ignoring them).

In fact, there is an easier approach to the problem. Since the probability of being found at a site depends on the degree of aggregation as well as on the mean, the null (the artifact model) assumes that aggregation at the chosen scale is constant (or at least that common species have the same distribution, and therefore mean, of aggregation as rare species). A trend showing that common species were less aggregated (lower $1/k$) than rare ones would show that common species were found at more sites than the null suggests, i.e., they have wider ranges than would be expected if they had the same life history characteristics as the rare ones. Such a trend might be considered interesting (although there might be many explanations – some trivial – for such a pattern). A trend showing that they were more aggregated would be even more interesting. It is worth noting that most of the studies performed to date use either snapshots of the spatial pattern of species or maps accumulated over some extended period of time. Both of these ignore the temporal variation of range (and mean density) that is typical of many groups of organisms. If such temporal information is available, examining each species separately and demonstrating life history phenomena for each and then searching for a trend for those over mean density would be more productive. The author discusses this in more detail in the section Relationships with Other Traits.

Trans-specific TPPs

Although Taylor’s power plots were originally defined for single species, it is possible to plot variance–mean relationships across species, with each species contributing a single point. Such plots are clearly difficult to justify if the area over which the data are collected is not equally relevant to all species and the means and variances used are not truly representative of the species. However, if these problems are ignored, then the trans-specific TPP can address the density–range problem by plotting the level of aggregation against mean density. The null described in the section Relationships with Other Traits now becomes equivalent to a TPP slope (β) of 2 or a horizontal line (slope = $\beta - 2$) on a $\log(1/k)$ versus $\log(\text{mean})$ plot. If $\beta < 2$ then aggregation appears to decline as mean density increases; the range of common species is greater than the null would suggest. However, before accepting an alternative of differences in the life history

characteristics of rare and common species, another null must be considered and rejected. If all the species have individual slopes $\beta < 2$ (a very unlikely event in most groups), then a trans-specific TPP will tend to have a slope of less than 2 as well, even if the rare and common species have the same life history characteristics. In most situations, it will be impossible to check this since if there were enough information to produce spatial variance TPPs for each species, it would be unnecessary to produce a trans-specific plot in which each species was represented by a single point. It would be more informative to fit separate TPPs and search for trends in the parameters.

Conclusions

The concept of density is an amorphous one. It has to be specifically determined for a particular purpose. The area used for both the sample unit and the study area is crucial and can only be determined after considering what aspect of density is relevant to the current study, and it may even then be difficult to determine since it depends on information about the species’ biology that may not be available (e.g., degree of aggregation and movement patterns). This makes comparisons across species especially difficult to interpret (particularly from published studies). That there is significance in all these patterns seems obvious, but interpreting them rigorously is a considerable (possibly insuperable) challenge.

Glossary

Allele One of several forms of a gene.

Chromosome A long, threadlike structure in the nucleus of a cell composed of DNA and protein.

Conspecific Of the same species.

Gene flow The incorporation of genes from one group of individuals into the gene pool of another group.

Gene pool The total of all genes in a group of individuals.

Origins and Detection

Populations are usually defined ecologically or genetically. The ecological entity is called a demographic unit, a group of individuals whose population dynamics are largely independent of those of other groups. The genetic entity is called a Mendelian population, a genetically distinguishable group of individuals evolving somewhat independently of other groups. Demographic units may be Mendelian populations and vice versa, but the two are not necessarily the same. Moreover, as is the case when defining any taxonomic boundaries, populations are not always clear, discrete units. Although the majority of individuals in a population breed with members of the same population, some individuals may move and interbreed with individuals from other populations, making a clear cutoff between most populations impossible. Because data about genetic populations are more readily available than that about demographic populations, here a genetic definition is used.

Just as populations can be defined in multiple ways, so can population diversity. Population diversity can refer to the amount of genetic diversity among a collection of populations. Populations that exchange genetic material frequently will not be as diverse as populations that are isolated, perhaps because of a geographic barrier, from one another. This article defines population diversity as the number of populations within a defined area and considers both the average number of populations per area for a species as well as total population diversity across the globe.

The following sections review the processes by which conspecific groups of individuals diverge into genetically distinct populations and how these genetic differences are detected.

Variability within Species

Much biodiversity exists within a species. This variation occurs at three different levels. First, there is a genetic variation within individuals of sexually reproducing species. Individuals carry multiple copies of most genes (two copies in diploid species such as humans), and these copies (alleles) may be different. Second, there is genetic variation between individuals. Except in the case of identical twins, no two individuals will have the

same alleles for every gene. Finally, there are genetic differences among populations. A population may contain alleles that other populations do not have and vice versa. In addition, two populations may differ in the proportion of individuals that carry alleles shared by both the groups.

Processes of Divergence

Individuals are not usually spread out evenly within a species' range but are clustered into localized groups. When these groups have limited genetic exchange, they may diverge into genetically distinguishable populations. (Methods to detect genetic divergence between populations are discussed later, *see* Importance.) Populations can diverge through drift and natural selection. These agents of microevolution result in genetic differentiation by acting on populations at different rates or in different directions.

Genetic Drift

Gene frequencies may change from one generation to the next simply because of chance. Particularly in a small population, random sampling error in the reproduction of alleles may contribute to changes in allele frequencies from one generation to the next. For instance, an allele that is only represented in a few individuals may be completely lost in the next generation if those few individuals by chance fail to reproduce or pass down that particular allele to their offspring. In addition, new alleles may be produced by mutation and increase in frequency in one group such that a unique allele is present in some groups and not others.

Natural Selection

Natural selection is the differential reproductive success of genetically different individuals resulting from the interaction of the individuals' inherited traits and their environment. Thus, different environmental conditions or biotic communities in a habitat can result in different selection pressures on populations. Some alleles may be beneficial to the reproduction of the individual carrying them in one population, whereas in another population the same allele may be relatively neutral or harmful to the carrier. In other words, selection in these two groups operates at different rates or directions, contributing to their genetic divergence.

Factors Influencing Divergence

Two factors, population size and dispersal, greatly influence the rate and importance of the previously mentioned agents of divergence. The smaller the population size, or number of individuals in a group, the greater the effect of genetic drift. The probability of gene frequencies in the next generation being representative of the previous generation decreases as the number of reproducing individuals decreases.

Dispersal, or the migration of individuals from one group to another, affects the amount of gene flow between groups. When an individual successfully reproduces in another group, the genetic composition of the new group becomes more similar to the group from which the immigrant originated. Thus, gene flow has the effect of homogenizing genetic composition, thereby decreasing the rate of divergence resulting from the three agents discussed previously.

Detection of Divergence

In general, the degree of genetic divergence between groups of organisms is measured by comparing the amount of variability within a group to the variability between groups. Thus, the genetic diversity embodied by the individuals in each group must be assessed in order to detect genetic divergence. Genetic diversity may be estimated indirectly by measuring morphological characteristics and migration rates or directly by examining the genetic material. A survey of some of these methods is provided in the following sections.

Morphological Variation

The variation that is observed among individuals is the result of their genetic composition, their environment, and the interaction between these factors. Thus, morphological variation will in some part represent underlying genetic variability, and it will also be intertwined with variation caused by environmental factors. Nevertheless, in the absence of direct genetic methods, morphological variation of a suite of traits is often used to resolve the population structure of a species. There have been attempts to tease apart genetic and environmental factors by using breeding experiments. In these studies, the environment is kept constant and morphological traits of parents and offspring are measured. One can then estimate the heritability, or the variation resulting from the genetic background, of a trait in the experimental conditions.

Migration Rates and Population Size

The migration rate of reproductive individuals into a group gives an estimate of the amount of gene flow, or exchange of genetic material, with outside groups. The lower the gene flow into a group, the greater the impact of genetic drift. The other critical factor affecting the degree of genetic drift in a population is its size: the smaller the population, the greater the expected drift. Thus, a combination of migration rate and population size estimates gives an indirect estimate of the amount of genetic divergence that occurs resulting from genetic drift.

Protein Variation

Currently, most studies on population differentiation examine DNA variation directly. However, before these methods became

cost-effective, researchers assayed protein (allozyme) variation among individuals between groups. The composition and structure of a protein are determined by the sequence of nucleotides (the subunits that make up the DNA molecule) comprising that gene. Alleles of the same gene have differences in their sequences, and each allele gives instructions for making a particular protein. The proteins can be distinguished by their rate of movement through a gel medium that is exposed to an electrical field. The movement rates of proteins differ because of different sizes and net charges of the molecules. By sampling many individuals in a group, one can assess the number of unique alleles and their frequencies. Thus, the genetic divergence between groups can be estimated from the variation of a random sample of proteins. The greater the differences in the proteins and their frequencies among groups, the greater the genetic divergence.

DNA Variation

Comparing the nucleotide sequence of particular genetic regions offers the greatest resolution of genetic differentiation. The genetic divergence between groups can then be estimated by comparing the similarity of the sequences among individuals in various groups. Usually, specific sections of an organism's DNA are targeted using the polymerase chain reaction (PCR) method. This section of DNA can then be examined by a variety of methods that vary in their resolution from sequencing to fingerprinting methods.

Fingerprinting methods have been commonly used when direct nucleotide sequencing was not cost-effective. For instance, restriction fragment length polymorphism analysis of a PCR-amplified gene region offers a broad examination of DNA differences among samples. The isolated DNA is exposed to proteins that break the DNA wherever a particular sequence of nucleotides occurs. The length of these fragments can be distinguished by their rate of movement through a gel medium that is exposed to an electrical field (similar to the method used to detect protein variation). The greater the difference in the pattern of fragment lengths, the greater the difference in the piece of DNA.

As the cost of sequencing continues to fall, met genomics approaches are also likely to become standard for population differentiation studies. This method does not target a particular gene (and therefore eliminates the problem of PCR biases) and instead involves sequencing random fragments from a pool of environmental DNA. The approach requires a large amount of computational power to organize and compare sequences among samples; however, this obstacle is quickly being reduced and computing power and storage becomes widely accessible to the researchers.

Indices of Divergence

A variety of indices are used to evaluate the population structure or the genetic divergence within a species. One of the most common indices reported is Sewall Wright's F_{ST} . This statistic can be calculated from the allele frequencies of a gene or genes and describes the variation among groups relative to the variation within the groups. The greater the variation that can be attributed to differences between groups rather than

within groups, the greater the F_{ST} value. Other measures of divergence describe the genetic distance between groups. These measures are indices of similarity or dissimilarity and are calculated using any of the types of data described previously, including protein frequencies and DNA sequences. Groups that are more isolated and for longer periods of time are expected to be more genetically distant.

Importance

Many of the benefits that biodiversity confers on humanity are delivered through population diversity. These benefits include esthetic enjoyment, species conservation, discovery and improvement of pharmaceuticals and agricultural crops, replenishment of stocks of economically valued species, and delivery of ecosystem services.

Again, population diversity is defined here as the number of populations in an area. Certainly, characteristics of a population, such as the area it occupies and the number of individuals it includes, will affect the benefits provided by a single population. In general, however, as the number of populations of a species increases, its area occupied and number of individuals increase. Thus, the following discussion focuses on numbers of populations and ignores population characteristics.

Esthetic Value

Populations of organisms, their physical environments, and the interactions between them make up natural ecosystems. People value the esthetic benefits of the populations in these habitats. For instance, bird watchers enjoy bird populations, hikers appreciate shade trees, and divers seek out reef fishes. Others simply enjoy the scenery created by the sum total of populations in an area.

Species Conservation Value

By definition, populations are essential to the conservation of species. Specifically, the number and size of populations influence the probability of species extinction; a species with many large populations is less susceptible to the extinction than a species with a few small populations. Migrants from other populations can prevent the extinction of a population by contributing individuals when numbers are low or supplying genetic variation needed to adapt to changing environmental conditions. If local extinction does occur, individuals from other populations can find a new population in the area. The threat of rapid global climate change makes population diversity within a species especially critical; a species with many populations is more likely to include the variation necessary to adapt to new conditions.

Genetic Value

Populations of the same species may produce different types or quantities of defensive chemicals, compounds that may be of medicinal or agricultural value to humans. The story of the

development of penicillin provides a clear example of the importance of population diversity to pharmaceuticals. The widespread use of penicillin as a therapeutic drug did not occur until 15 years after Alexander Fleming's discovery of the compound in common bread mold. One reason for this delay was a search to find a population of the mold that produced greater quantities of penicillin than did the original population.

Population diversity among wild crop relatives supplies genetic material to agricultural strains. The world's three main crops (rice, wheat, and maize) are widely planted in genetically uniform strains. The emergence of a new disease or pest can therefore threaten large fractions of the harvest at a time. Wild crop relatives contain genetic variation that does not exist in the agricultural populations, including genetic resistance to a variety of diseases and pests. Thus, when an agricultural strain is susceptible to a disease or pest, researchers search for genetic resistance in wild crop relatives. Thousands of populations may have to be tested until one is found that carries the genetic resistance that can be used to protect the crop. For example, when the grassy stunt virus emerged as a serious threat to the rice crop in Southeast Asia in the late 1960s and 1970s, a search for resistant rice varieties was conducted. Only one strain of a wild rice at the gene bank of the International Rice Research Institute was found to resist the virus. Genetic variation in wild populations will also be crucial in providing genetic material to sustain crop yields in the face of human-induced changes in growing conditions.

Direct Economic Value

The reduction of economically important species often has direct consequences for local peoples. For instance, the decline of fish harvests leads to the loss of income for fishermen and the loss of an important source of protein for much of the human population. Populations of economically valued species not only act as a safety net against species extinction but also increase the species' harvest level. If more populations exist, then more populations can be harvested. Populations may also increase harvests indirectly. A collection of populations that are connected by dispersal is called a metapopulation. In a metapopulation, dispersal of individuals from other populations can rescue a population from extinction when its numbers are critically low. Over the long term, a population will be larger if it is a component of a larger metapopulation than if it is part of a smaller metapopulation or completely isolated.

Ecosystem Service Value

Ecosystem services – services that natural ecosystems provide to human civilization for free – are perhaps the most important benefits that populations confer on humanity. They include natural processes such as purification of air and water, detoxification and decomposition of waste, generation and maintenance of soil fertility, pollination of crops and natural vegetation, and pest control. Populations deliver these services, and therefore population diversity at global, regional, and local scales affects the quality and quantity of the services

provided. (Except where stated below, this article focuses on how the number of populations affects ecosystem services, although the size, density, and genetic composition of populations are also important factors.)

Global Population Diversity

Higher global population diversity probably enhances the delivery of global ecosystem services such as regulation of biogeochemical cycles and stabilization of climate. For example, the larger the area remaining under natural tree cover in the Canadian taiga, the greater the amount of carbon stored there. Although deforestation in this region may not result in the extinction of any tree species, a large-scale loss of tree populations would affect the global balance of greenhouse gases in the atmosphere.

Regional Population Diversity

For many ecosystem services, global population numbers will not be as important as the population diversity in the region of interest. For these services, it is necessary not only that there be many populations somewhere in the world but also that they exist in the region where the services are to be provided. These services include water purification by forests and wetlands and mitigation of floods and droughts by forests. Loss of these services occurs when the populations in forest and wetland habitats are destroyed in one area, regardless of the continued existence of these populations elsewhere.

New York City provides an excellent example of the value of regional population diversity for water purification. The city was renowned for its clean water, which came from the Catskill Mountains 100 miles to the north. Natural purification processes, performed by populations of plants and soil organisms, were sufficient to cleanse the water for most of the city's history, but in recent years land development and related human activities reduced the effectiveness of these processes. In 1996, city water officials floated an environmental bond issue to purchase land, freeze development on other lands, and subsidize the improvement of septic tanks. It is expected that these actions will restore and safeguard the local populations of the organisms that filter and purify the water. If so, an investment of \$1 billion in natural purification services will have saved city taxpayers \$6–8 billion, the additional avoided cost (more than 10 years) of building a water treatment plant.

Regional population diversity is also essential for pest control. This function of populations is easy to take for granted, but it is dramatically illustrated when one kind of organism is transplanted to a new environment that lacks populations of predators that usually keep its numbers in check. A classic case is the importation of prickly pear cacti (*Opuntia*) into Australia by early settlers. In the absence of their normal predators, the cacti spread more than approximately 25 million ha in New South Wales and Queensland. About half of the area was so densely covered with the cactus that the land could not be used for farming or ranching, and the costs of poisoning or removing the *Opuntia* were more than the value of the land. The problem was solved by importing a cactus-eating moth, *Cactoblastiscactorum*, from the South American homeland of the *Opuntia*. Once regional populations of the moth were established, the *Opuntia*

populations were decimated. Although the cactus can still be found in Australia, it now occurs only as scattered clumps.

The importance of regional populations of native pollinators for agriculture is made clear by their decline (chiefly a result of pesticides and habitat destruction). For example, for more than 60 crops grown in the US, farmers have to pay honeybee keepers to bring hives to the fields or orchards to be pollinated. This service is estimated to cost farmers more than \$60 million a year and the federal government more than \$80 million in subsidies. Problems within the bee-keeping industry (disease and hybridization with the Africanized honeybee) are increasing these costs.

Local Population Diversity

The number of populations at a particular location – the local diversity of species – affects local ecosystem function. In many greenhouse and field experiments, plant productivity has been found to increase with the diversity of plants. Higher diversity also seems to be associated with greater stability of plant productivity. For instance, more diverse grasslands appear to be more resistant to drought and grazing disturbance than less diverse areas. Thus, local population diversity likely influences the amount and variation of services provided by an ecosystem. Also, because regional and global services are performed by an assemblage of local ecosystems, this scale of population diversity will affect the delivery of larger scale services as well. For example, global biogeochemical cycles are probably influenced not only by the total number of tree populations on the planet but also by the diversity of trees within a habitat.

Furthermore, traits that affect local ecosystem functioning may differ among populations. [Treseder and Vitousek \(2001\)](#) studied multiple populations of two ecologically important tree species in Hawaii. They found genetically based differences among populations of *Metrosideros polymorpha* in the decomposability of leaf litter and among populations of *Acacia koa* in the potential to fix nitrogen. Thus, these populations are not interchangeable; if they were replaced with other populations of the same species, the functioning of the native ecosystem would be altered. Indeed, there is a growing literature on the importance of genotypic diversity within and among populations for ecosystem functioning and the delivery of ecosystem services. For instance, [Schindler et al. \(2010\)](#) found that the presence of genetically distinct sockeye salmon populations in Alaska stabilizes (reduces the variability of) total fishery abundance within and among watersheds. Thus, high population diversity translates into fewer fishery closures and greater economic value.

Extent

Although populations are critical to humanity, little is known about the extent of population diversity. [Hughes et al. \(1997\)](#) made a rough estimate of the total number of populations on the planet. They used a Mendelian population definition and restricted the estimate to eukaryotes (although the diversity of bacteria and viruses is probably enormous, information on their diversity is scarce).

The evaluation of global population diversity involved three steps. First, they estimated the average number of populations per unit area from literature on population differentiation. Second, they calculated the average range size of a species from published range maps. The product of these two numbers yields an approximation of the average number of populations per species. Finally, they multiplied this product by the number of species on Earth to arrive at an estimate of global population diversity.

Populations per Area

To quantify the number of populations per area for an average population, *Hughes et al. (1997)* searched 15 journals for genetic studies on population differentiation. They found 81 articles that provided appropriate data to quantify the number of populations per area. Most of the species were vertebrates (35), followed by plants (23), arthropods (19), mollusks (4), and a flatworm. For each species, they determined whether the sampling locations in the studies were for separate populations or a single population. If the genetic differentiation between localities was statistically significant, then all the localities were called separate populations. The number of populations per area was calculated as the number of sampling points divided by the area that was sampled. If the samples were not significantly differentiated, then it was assumed that all of the samples were taken from one population and that the size of a population was the size of the sampling area. For many species, an intermediate amount of differentiation was found. For example, although not all the samples were significantly different, some clusters of sampling locations were significantly different from others. In this case, the number of significantly diverged clusters was used as the number of populations.

Average Range Size

The average range size of a species was calculated from more than 2400 species range maps for birds, mammals, fish, and butterflies. Weighting each of the taxonomic groups equally, the mean range size of a species is 2.6 million km². The average range size of the most species-diverse group, the butterflies, is 2.2 million km² and this was conservatively used as the estimate of the average range size of a species.

The shaded areas of species distribution maps almost always include habitats in which populations do not occur. Therefore, estimating species' ranges from these maps will probably inflate the population diversity estimate. In addition, the majority of species included occurred in temperate regions; however, it is estimated that two-thirds of species diversity exists in the tropics. Because species' range sizes in some taxa tend to increase toward the poles, the bias toward temperate areas may inflate the estimate of average range size. In contrast, the range maps that were used were restricted to one continent; therefore, the range sizes of intercontinental species were probably underestimated.

Species Diversity

The product of the average number of populations per area and the average range size of a species gives an average of 220

populations per species. Multiplying this number by three estimates of global species richness (5, 14, and 30 million) yields estimates of 1.1, 3.1, and 6.6 billion populations globally. This calculation assumes that a species' range size and its number of populations per area are independent. If these two factors are strongly correlated, however, the estimate may be quite inaccurate. However, it is not known whether a correlation exists, let alone whether the correlation is positive or negative.

Human-Induced Changes

With the expansion of the human enterprise, human beings are having a significant impact on population diversity. Populations are being both created and destroyed on a large scale as a direct result of human activities. As species are introduced to nonnative habitats, new populations are formed. At the same time, habitat disturbance and destruction are driving the extinction of populations. Although most public and scientific attention to biodiversity is centered on species, a few recent studies have attempted to evaluate the extent to which humans are modifying population diversity.

Introductions and Extinctions in Western Australia and California

Hobbs and Mooney (1998) collected data on the deletions and additions of populations in Western Australia and California. They gathered records of species that are threatened, extinct, or introduced in these areas. The number of regional extinctions gives a very conservative estimate of population extinction since most, if not all, of the species originally had more than one population in the region. Similarly, it is reasonable to assume that the threatened species have already lost populations. These species are endangered in large part because of range contractions – that is, the extinction of populations, thereby reducing the geographic distribution of the species. The number of introduced species is also a lower bound estimate of the number of new populations. To be recorded as an introduced species, at least one population must be established, but many species may have already established multiple populations.

For California, *Hobbs and Mooney (1998)* gathered data for butterflies, amphibians, reptiles, birds, mammals, and plants. Of 8274 total species, 1109 are introduced (13.4%), 71 endangered, and 49 extinct. The endangered and extinct categories include subspecies, which are most certainly genetically distinct populations. For Western Australia, the study reported information for plants, mammals, birds, reptiles, amphibians, and freshwater fishes. Of more than 12,000 plants, 1032 have been introduced, 232 are threatened, and 52 have gone extinct. The percentage of all introduced species is 7.3%, which is lower than that in California. In California, no extinctions have been reported for reptiles and amphibians, and in Western Australia no extinctions have been recorded for birds, reptiles, amphibians, or freshwater fishes. As mentioned previously, however, these results mask most of the population extinctions. In the groups for which no extinctions were

Figure 1 Predicted relationships between the area of habitat destroyed and the extant number of species and populations. The species curve (solid line) is $S = cA^z$ (see text), where z is 0.30. The population curve (dashed line) is linear.

recorded, other studies report significant species' range contractions. For instance, the loss of native vegetation in Western Australia has resulted in range contractions and population extinctions of species that rely on this habitat.

Extrapolating Population Extinctions from Tropical Deforestation Rates

Most estimates of species extinction rates are based on species–area relationships and the rate of habitat loss due to deforestation. The most commonly used model of the species–area relationship is shown in **Figure 1**. This model is $S = cA^z$, where S is the number of species, A is the area (or habitat size) in which the species are found, and c and z are constants estimated from empirical studies. This model is in agreement with a multitude of empirical studies on a variety of taxa and scales. With this formula, the rate of species extinction in an area can be approximated from the rate of habitat loss. **Figure 1** also illustrates a widely cited rule of thumb: A decrease in habitat area by 90% should result in a decrease in species diversity by approximately 50%.

Population–Area Relationship

There is no comparable work describing a population–area relationship, but most studies assume that population numbers and area probably correspond approximately in a one-to-one manner. The basis for the difference between the species– and population–area relationships is their size; a population occupies a small area relative to a species. When a substantial amount of habitat is destroyed, populations that were encompassed by the area will be lost. In contrast, many fewer species will go extinct because other populations of the species exist elsewhere. Thus, the rate of population extinction will be faster than that of species extinction. If the one-to-one relationship does hold, then when 90% of an area is destroyed about 90% of the populations in the original area will be lost, in contrast to only 50% of all species (**Figure 1**).

Extinction Rate

The rate of population extinction in tropical forest regions can be estimated with the population–area relationship in **Figure 1**. Assuming that tropical deforestation is occurring at 0.8% per year, global population diversity is 3 billion, and two-thirds of all populations exist in tropical forest regions, *Hughes et al. (1997)* calculate that 16 million populations per year, or approximately 1800 per hour, are being exterminated in tropical forests alone. This rate is three times higher than conservative estimates of species extinction.

These high extinction rates are supported by more current studies that use different approaches. *Ceballos and Ehrlich (2002)* investigated mammalian population extinction using historic (nineteenth century) and present-day range distribution of 173 declining mammal species from six continents. They found that together these species have lost more than 50% of their range area. Assuming that loss of range area is a result of population extinctions, these losses are much higher than species extinctions.

Loss of Genetic Diversity within Populations

These above studies focus on the extirpation of populations, rather than the total amount of genetic diversity of the remaining populations. Further work suggests that even populations that do remain may contain less genetic diversity. For instance, *Garner et al. (2005)* compared heterozygosity of healthy versus demographically challenged mammal populations and found that species that had experienced a demographic threat had significantly reduced mean heterozygosity (26% in marsupials and 22% in placentals).

Ameliorating Changes in Population Diversity

There are a variety of ways in which human modification of population diversity can be slowed and its impacts alleviated.

Controlling Invasions

In general, the impact of newly introduced populations on an ecosystem is highly unpredictable. In fact, most invasions do not produce noticeable effects. The invasive species that do have significant impacts, however, can cause widespread ecosystem disruption and economic loss. In theory, removing invasive populations can restore the native ecosystem (unless species have gone extinct). In practice, however, complete removal or even partial control of invasives is rarely successful. One of the few examples of a successful program to control invasive populations is the *Opuntia* cactus case described previously (*see Importance*).

There are three broad methods to control invasive populations: biological, chemical, and manual. One reason that introduced species can be very harmful to an ecosystem is that the species are free from their natural enemies and therefore overabundant. Biological control involves reducing the invasive species' numbers by introducing a predator or parasite from its native habitat. Chemical controls are poisons (usually synthetic) such as pesticides and herbicides. Manual control entails the physical removal or killing of individuals. All three of these fixes are usually expensive and in the case of

biological and chemical controls risk doing more harm than good to the ecosystem. An introduced predator might attack native species, and chemicals may harm native species or human beings. Thus, the best control is to prevent invasive populations from establishing in the first place. Unfortunately, this is an extremely difficult challenge – most introductions are accidental. Furthermore, with the accelerating movement of products and people around the world, the rate of introductions will certainly increase in the future.

Preservation

Protecting intact habitat from destruction or degradation is the most straightforward method to prevent the extinction of populations. If population diversity and habitat area are indeed related in a linear manner, then the more land that is preserved, the more population diversity is protected. In most cases, however, limiting almost all human access to a piece of land is usually not feasible because of competing uses, such as agriculture and urbanization. Nevertheless, these competing uses do not eliminate all prospects of conserving population diversity and the benefits they provide. In fact, in some parts of the world, many populations appear to be surviving in the countryside – that is, in human-dominated areas (e.g., Sekercioglu *et al.*, 2007). Thus, a promising approach involves managing the countryside to prevent further degradation (and perhaps some restoration) of population diversity in these areas.

Restoration

Unlike species, populations can be restored and, along with them, at least some of the benefits that they once provided. Although genetic variation unique to the extinct populations

will be lost, groups of individuals can be reintroduced to an area and in a relatively short time may evolve significant genetic differences from other populations. Reestablishing populations of a native species is not a simple task, however. Often, the native ecosystem is degraded and little is known about the biological requirements of the species.

Glossary

Allee effect Reduction in growth rate of a population at low densities.

Competition The effect of the members of one species reducing the growth rate of the population of another species through interference or exploitation of common resources.

Density dependence Effects on the growth rate of a population due to interactions among the members of that population.

Endogenous forces Forces within a population that affect the dynamics of the population.

Exogenous forces Forces outside a population that affect the dynamics of the population.

Population Members of a single species that can potentially interact with each other.

Predation An interaction between two species in which one species consumes the other.

Introduction

The term *population* refers to the members of a single species that can interact with each other. Thus, the fish in a lake, or the moose on an island, are clear examples of a population. In other cases, such as trees in a forest, it may not be nearly so clear what a population is, but the concept of population is still very useful.

Population dynamics is essentially the study of the changes in the numbers through time of a single species. This is clearly a case where a quantitative description is essential, since the numbers of individuals in the population will be counted. One could begin by looking at a series of measurements of the numbers of particular species through time. However, it would still be necessary to decide which changes in numbers through time are significant, and how to determine what causes the changes in numbers. Thus, it is more sensible to begin with models that relate changes in population numbers through time to underlying assumptions. The models will provide indications of what features of changes in numbers are important and what measurements are critical to make, and they will help determine what the cause of changes in population levels might be.

To understand the dynamics of biological populations, the study starts with the simplest possibility and determines what the dynamics of the population would be in that case. Then, deviations in observed populations from the predictions of that simplest case would provide information about the kinds of forces shaping the dynamics of populations. Therefore, in describing the dynamics in this simplest case it is essential to be explicit and clear about the assumptions made. It would not be argued that the idealized population described here would ever be found, but that focusing on the idealized population would provide insight into real populations, just as the study of Newtonian mechanics provides understanding of more realistic situations in physics.

Density-Independent Dynamics of a Single Species without Age Structure

The very simplest description of population dynamics looks only at a single population of a single species. Thus,

complications due to the effect of one species on the growth or dynamics of another are initially ignored. Any differences among individuals within the species are assumed insignificant. Thus, differences in age, sex, genetics, spatial location, and other individual characteristics are all ignored. Moreover, a single population is focused on, so any effects of immigration or emigration are ignored as well. Any effect of randomness is also ignored, which might arise either from the effects of small population sizes or environmental variability.

However, one more fundamental assumption has to be made when describing the dynamics of a population in order to consider what effect members of the population have on each other. The simplest case is density independence – in which the demography of the population does not depend on the size (in numbers) of the population. It is assumed that the per capita rates or numbers of births and of deaths do not depend on the size of the population. This is not the same as assuming that the overall birth and death rates do not depend on the population size, but it is equivalent to assuming that the overall birth and death rates are proportional to the population size.

To describe these dynamics under these assumptions in detail, the discussion needs to be split into two cases, depending on the way reproduction occurs. For some species, such as humans or many microorganisms, births and deaths occur essentially continuously through time. For other species, such as many butterflies or annual plants, organisms reproduce once each year and then die. These two possibilities are treated separately and the author then turns to more complex cases.

For the case of overlapping generations and continuous reproduction, the description of population dynamics can be written using the verbal equation

$$\text{Rate of change of population} = \text{Rate of births}$$

$$- \text{Rate of deaths}$$

With the assumption of density independence, the rate of births can be written as bN , where b is the per capita birthrate and N is the population size. Similarly, the rate of deaths is mN , where m is the per capita death (mortality) rate. The verbal equation can then be written as the mathematical

equation

$$dN/dt = bN - mN$$

or, letting $b-m=r$, the intrinsic rate of increase (or “little r ”) as

$$dN/dt = rN \quad [1]$$

An explicit solution to this model, expressing the population size at any future time t in terms of population size at time 0 and the intrinsic rate of increase, r , can be determined. The solution of the model [1] is exponential growth, namely

$$N(t) = N(0)e^{rt} \quad [2]$$

where e is the base of the natural logarithms, $N(0)$ is the population at time 0, and $N(t)$ is the population at time t . The ecological implications of this formula will be focused on after the alternate case of growth in discrete time is discussed.

For the case of nonoverlapping generations, appropriate for annual plants, a verbal model can be written as follows:

Numbers next year = Per capita reproduction times
numbers this year

In mathematical terms, this equation becomes

$$N(t+1) = RN(t) \quad [3]$$

where $N(t)$ is the population size in year t , and R is the number of individuals in the population next year produced by each individual in the population this year. This model, too, can be solved explicitly,

$$N(t) = R^t N(0) \quad [4]$$

which is geometric growth. In fact, if the growth rates in the two cases were matched so that $R=e^r$, or $\ln R=r$, the two population descriptions [2] and [4] would provide exactly the same numerical values (at the discrete times $t=1, 2, 3$, etc.).

The implications of solutions [2] and [4] are not that it would be expected that any real population grows at these rates, but, as emphasized perhaps first by Malthus several centuries ago, that exponential or geometric growth is very rapid. If r is positive or R is greater than 1, after relatively short times, the predictions of exponential or geometric growth are that populations will become very large. Thus, exponential growth cannot last, and the fundamental question of population dynamics becomes what prevents exponential growth and what are the consequences for population dynamics of these forces that prevent exponential growth.

Long time density-independent growth in natural systems obviously does not occur, with the closest examples following introduction of nonnative species. For example, the number of collared doves in Great Britain increased exponentially from less than 10 to more than 10^4 from 1955 to 1963, but the population essentially stopped growing shortly thereafter. Other introduced species have behaved similarly.

Density-Independent Age or Stage Structure

There are many ways to extend our understanding of the dynamics of a single population from the simplest cases of

density-independent growth that have just been covered, and to explore what prevents exponential growth. There are two basic ways to extend our model for a single species (and remain within the context of looking at a single species). The effects of members of the population on each other and how they affect the dynamics could be looked upon. Also, the effect of differences among members of the population on the dynamics of the population could be previewed. The effect of differences among individuals, focusing on differences due to age, will be reviewed first. Other differences are also important and age is also focused on because it is a critical factor, has been well studied, and is easy to understand and measure. Does including the effect of age prevent exponential growth?

It is clear that within many populations some individuals are too young to reproduce, whereas others are too old. Thus, just looking at the numbers of individuals in the population is not enough to predict the future numbers. When looking at the effects of age structure, the proportion of females and males affecting the growth of the population is also an issue. Since the role of density dependence will still be ignored, the approach of only looking at the female members of the population will be considered, and therefore only looking at births of females to females. Thus it is implicitly assumed that males do not affect the dynamics of the population, which may be valid for some natural populations, such as moose, but not all, such as birds with parental care.

The information the author wants to include is the probability of births (or rate of births in continuous time) to a female of a given age, and the probability (or rate) of death at each age. From this information, and from the current distribution of females of different ages in the population, it should be possible to predict the future population. Once again, there are different formulations for this model, depending on whether the model is phrased in continuous or discrete time.

In discrete time, one way to write this model is known as the Leslie matrix model. A census interval, for example 5 years in humans, is first decided on. The population is described by a vector (which is just a vertical list of numbers) in which each entry is the number of females in each age class, 0–5, 6–10, 11–15, 16–20, and so on. The length of the age classes and the census times have to be the same. Then from the data, the average number of births to, and probability of survival of, a female in each age class is determined, over a 5-year interval. These data are presented in a life table, which summarizes the relevant demographic information. Life tables have been constructed from numerous species, ranging from insects, to small mammals, to long lived reptiles, to plants, and to humans. The data in a life table can be used as the entries in a matrix, known as the Leslie matrix, in which the first row are the birthrates, and the entries under the diagonal are the survival probabilities.

Analysis of this model reveals information about both the rate of growth of the population and the distribution of individuals of different ages. The key concept is the stable age distribution – the unique proportions of individuals of different ages that are preserved through time in the model. Thus, if the population starts at the stable age distribution, it will remain in the stable age distribution. Also, for a population in the stable age distribution, the proportional change in the numbers in each age class, and therefore the population as a

whole, is the same at each time step. This is simply geometric growth once again.

What happens if the population is not in the stable age distribution? It is clear that then the growth rate may change through time and will depend on the ages of the individuals – for example, a human population of all 0–5-year-olds would have no births, whereas one composed only of 20–25-year-olds could have many births. Yet, under some simple assumptions (essentially that reproduction is not confined to a single age class), if the population does not start in the stable age distribution, it will approach the stable age distribution through time. The result is that geometric or exponential growth occurs again, but only in the limit.

The analogous model in continuous time provides similar results, though there is a difference in the conceptual development. In this case, which can be traced back several centuries to the work of the Swiss mathematician Euler, the focus is typically on the rate of births through time rather than the individuals of all ages at a single time, through the use of a renewal equation. In words, the dynamics are described as

Rate of births at time t = Sum over all ages j of the birthrate
at time $t-j$ $\times$ the probability of surviving to age j $\times$ the
birthrate at age j .

Using the assumption of exponential growth this equation can be reduced to an equation for the growth rate of the population, the Euler–Lotka equation. This equation (or its discrete time approximation) is the basis for most estimates of the growth rate of populations.

The demography of populations and the ways in which population growth rates are calculated are worth emphasizing because they play a central role in conservation biology. A calculation of the growth rate of a population is often used to determine if the population is endangered. By looking at the effect of changes in different demographic parameters on the growth rate, one can determine which conservation efforts may have the largest effect on the growth rate and therefore the survival of the species in question.

Often, age is not a sufficient or appropriate descriptor of differences among individuals, and a classification based on stage (which could be weight, or some other characteristic) is more appropriate. Models incorporating stage can be more realistic, but care is needed to ensure that the dynamics are appropriately described. Recent advances have focused on using a continuous description of stage, particularly in discrete time using integro-difference equation models. This approach goes by the name of the integral projection model.

Density Dependence

Continuous Time

We now need to continue our search for processes that will prevent populations from growing exponentially and what the consequences of these limiting processes are for population dynamics. The simplest answer is that as the density of a species increases, either the birthrate goes down or the death rate goes up, because the members of the species compete

Figure 1 Explicit solution of the logistic equation with $r=1$, $K=100$, and $N(0)=1$.

with each other (due to the fact that the food supply or some other resource is limited). This kind of intraspecific competition is one of the fundamental reasons why populations may not grow exponentially, and its consequences will be explored, both for species with overlapping generations and those that reproduce once per year. In both of these cases and all that follows the age structure will be ignored, for simplicity.

One of the earliest formal descriptions of these dynamics was given by Verhulst, who produced what is now known as the logistic equation. In this equation, the growth rate of the population is described by the product of the exponential growth term as in model [1] and the term representing reduction in per capita reproduction due to interactions with other individuals. In modern terms, the model is written as follows:

$$dN/dt = rN(1 - N/K)$$

where the term K is called the carrying capacity of the population.

The logistic equation can be solved explicitly (Figure 1), but the most important conclusion is that any population reaches the carrying capacity, K . This qualitative conclusion also holds for similar assumptions. The search for the mechanisms leading to density dependence, and even direct evidence for density dependence in natural populations, is difficult.

Another aspect of density dependence is to reduce population growth rate at low population levels, perhaps through difficulties in finding a mate. This concept, the Allee effect, provides a lower limit to population size. If the population is too small, it may actually decline and thus can go extinct. The importance of Allee effects has been increasingly recognized, especially as a concept that underlies extinction.

Discrete Time

An alternate formulation based on the discrete time leads to very different conclusions. Here the idea is that the number of individuals next year will simply be a function of the number of individuals this year, with density dependence. The history of models like this began with examples from fisheries, such as the Ricker model:

$$N_{t+1} = N_t e^{r(1-N_t/K)}$$

The dynamics and behavior of this model are captured in the behavior of a much simpler model, the quadratic model, usually written as follows:

$$x_{t+1} = rx_t(1 - x_t)$$

where x_t is a scaled measure of population size and r is a measure of the rate of population growth. The density-dependent or carrying capacity parameter is absorbed in the scaling of x_t . Beginning with work of Robert May in the early 1970s, much of the interesting behavior of this model and its implications for population dynamics were elucidated.

The dynamics of density dependence in discrete time differ greatly from those in continuous time because of the presence of the implicit time delay imposed by the discrete time framework. As the population tends toward equilibrium, it can overshoot the equilibrium, with striking consequences. The overall dynamics of the quadratic model as a function of the parameters is as follows. If the growth rate is too low, $r < 1$, the population will die out. If $1 < r < 2$, the population monotonically approaches an equilibrium.

For larger values of the growth rate, the dynamics differ from the continuous time model. If $2 < r < 3$, the population approaches an equilibrium, but in an oscillatory fashion. For $r > 3$, different dynamics emerge. At first the population exhibits stable cyclic behavior of alternating low and high years. For still larger values of r , the population has cycles of longer period, until above about $r = 3.57$. For these large values of r , the population is typically chaotic, meaning that the population fluctuates and exhibits very sensitive dependence on initial conditions.

The search for this kind of behavior in natural populations has proven very difficult, but the attempts have greatly increased our knowledge of population dynamics. Laboratory populations including flour beetles have been shown to behave chaotically. Further study of this phenomenon is discussed later in the context of disease dynamics.

Role of Stochasticity

The discussion so far has assumed that no chance, or stochastic, factors play a role in the dynamics of the population. In many cases, this is far from the truth. For very small populations, demographic stochasticity, resulting from the chance that many births or deaths in a row might occur, has a large effect on the dynamics. In small populations, extinction may occur by chance even if the expected outcome would be for the population to grow.

A second important source of variability is the influence of the environment. Random fluctuations including year-to-year variability in weather, can cause large changes in the growth rate of a population.

A third kind of stochasticity is demographic heterogeneity, which is fixed differences in vital rates between individuals. This can be difficult to distinguish from environmental variability since both typically lead to a negative binomial description in the distribution of population sizes. However, demographic heterogeneity leads to greater variances at small population sizes, and therefore much greater extinction risk.

All of these stochastic effects need to be taken into account to understand the dynamics of natural populations. Historically, ecologists phrased this as a dichotomy, asking whether density-independent stochastic (e.g., weather) or density-dependent deterministic factors were responsible for controlling populations. The more modern version of this question is discussed later in the context of disease dynamics.

The Simple Two-Species Interactions

Overview and Definitions

Thus far, the focus is only on effects of the environment or within a single species, intraspecific interactions, on population dynamics. A fundamental question is, what is the role of interspecific interactions on population dynamics? The consequences of the interactions among many species fall within the realm of community ecology, but many of the simple effects of species interactions can be understood by taking a population dynamic approach, starting with the interactions between two species. This study will begin to highlight the important issue of which interspecific interactions act to prevent exponential growth of natural populations. The study of the interactions between two species has a long history in ecology, beginning with the seminal theoretical work of the American Lotka and the Italian Volterra, and the experimental work of the Russian microbiologist Gause.

The first step in a study of two-species interactions is to classify the interactions, primarily according to the effects each species involved has on the other. The dynamical effects of each interaction are then outlined. An interaction where one species eats another, such as wolves preying on moose, is called a predator-prey interaction. The predator gains a benefit and the prey is harmed. Interactions between herbivores and plants also are similar, so these interactions can more generally be called exploiter-victim or consumer-resource. The interactions in which one species is harmed and one gains will be treated separately because their dynamics are different or special. One of these is the interaction between disease-causing organisms and their hosts, and the other is the interaction involving insects (parasitoids) that lay their eggs inside the developing stage of other insects (hosts).

A second important two-species interaction is between two species that share a resource, such as two species that eat the same food items. This is a competitive interaction, where each species reduces the growth rate of the other. The resource, that is, the object of competition can also be nonbiological, such as light or water for plants or nutrients. Other competitive interactions might be more active and involve the production of chemicals, which would harm the competitor.

A third kind of two-species interaction is one in which both species benefit, as might occur between a pollinator and the species it pollinates. The pollinator gains, typically, a food resource, and the species being pollinated is aided in its reproduction. This is known as mutualism.

This classification does not exhaust possible two-species interactions, but these are the major interactions that have been the subject of most study. Many of the dynamical

consequences of other interactions can be deduced by considering the cases that have been outlined.

Predation

The discussion now turns to the dynamical effects of each interaction, beginning with the predator–prey interaction. The description of these dynamics began with the work of Lotka and Volterra, and this discussion starts with the simplest case they considered. It is assumed that in the absence of the predator, the prey population grows exponentially, in accordance with our examination of the single species case earlier. In the absence of the prey, it is assumed that the predator population declines exponentially. To complete the description of the dynamics, only the interaction between the predator and the prey and the consequences for the dynamics of both populations have to be described. The simplest case is to assume that encounters between predator and prey are random, so they occur at a rate proportional to the size of each population. It is also assumed that there is a fixed probability that the prey is killed in such an interaction, and that each prey individual that is killed contributes a fixed amount to the rate of growth of the predator population. These assumptions lead to the classic equations

$$dH/dt = rH - bHP$$

and

$$dP/dt = cbHP - kP$$

where H is the size of the prey population, P is the size of the predator population, r is the intrinsic rate of increase of the prey in the absence of the predator, k is the death rate of the predator population in the absence of the prey, the encounter rate is proportional to b , and c measures the conversion of prey deaths to increases in the predator population.

The analysis of the model shows that there is an equilibrium, but that the equilibrium is neutrally stable. Thus, all other solutions cycle. From this analysis, the important conclusion is that the predator–prey interactions lead to cycles is depicted, but the model is unsatisfying because the solution depends completely on the initial conditions. The cycles essentially result from delayed feedbacks.

Modifying the model changes the conclusions from the unsatisfying one of neutrally stable cycles. If the equations are modified so that there is density dependence in the prey population, the system approaches equilibrium in an oscillatory fashion. Changing the description of the consumption of prey by predators can then produce stable cycles. This presence of cyclic behavior is the most important conclusion from the study of predator–prey interactions.

There are numerous examples of interactions between predator and prey in natural systems, which at least exhibit a tendency toward cyclic behavior, ranging from the classic example of hare and lynx in Canada to wolves and moose on Isle Royale. The observations in many of these cases are somewhat equivocal because it is often difficult to determine what is really causing the cycles, partly because it is difficult to isolate a single predator–prey pair within a larger community.

Host–Parasitoid Dynamics

By contrast, there is another kind of exploiter–victim relationship that does have more tightly coupled species interaction. The overwhelming majority of animal species are insects, and approximately one-fifth to one-sixth of all insect species are parasitoids: they have a life cycle where they lay their eggs in the developing stages of other insects, the hosts, and consume them from within, so the host is killed and one or more adult parasitoids emerge. Many insect pests of crops have important parasitoids. The interaction between a host and a parasitoid is essentially another version of the interaction between a prey and a predator, but the approach and the questions are somewhat different, so this case is treated separately. Here, the typical approach is discrete in time, which is appropriate for host insect species with single generations per year. The host species is assumed to grow exponentially (or geometrically) in the absence of the parasitoid. Unlike the predator–prey interaction, the parasitoid life cycle is tightly coordinated with the host because the parasitoid lays its eggs in the developing host. Thus the dynamics of the interaction are described by the probability that an individual host is parasitized, which could depend on the population density of the host and of the parasitoid.

The equations describing this interaction were first developed by Nicholson and Bailey, but these initial equations predicted that the populations would be unstable with cycles of ever-increasing amplitude. Thus, efforts since then have been focused on determining what would allow host and parasitoid to persist in a stable fashion. Suggestions like aggregation of host or parasitoid, or density dependence have been studied in models. Yet, as recent careful work by Murdoch and his colleagues on red scale and its parasitoids in California shows, the search for the stabilizing feature in natural systems is quite difficult. This is a system where a host and its parasitoids coexist stably, yet the search for the mechanisms that stabilize this interaction has been able to reject many of the conventional explanations.

Disease Dynamics

Another very important interaction that is similar to the predator–prey system is the interaction between diseases caused by bacteria or viruses and their hosts. However, in this case the focus is very different, since the number of disease organisms is not counted and instead only the number of diseased hosts is counted. These systems have become very important subjects of study in population biology partly because of very good records of the number of diseased individuals, in particular for human diseases.

The classic models in this area, which go back to the early work of Kermack and McKendrick in the 1920s, break up a population into three categories: susceptible, those individuals that can become infected; infectives, those individuals which are infected and infect others; and removed, those individuals which no longer can infect others. The simplest case is to look over relatively short times, so that overall population sizes are constant, and look at epidemics. The models, called SIR models, are framed in terms of differential equations where the key parameters are the contact rate, the recovery rate, and

the total population size. The rate of infection is assumed to be equal to the product of the contact rate, the number of susceptibles, and the number of recessives. The recovery rate for individuals is assumed to be just a constant. Then the dynamics depend on a single nondimensional parameter, the reproductive number, R_0 , which is the number of new infectives produced by each infective, when the population is essentially composed of all susceptible individuals. If R_0 is less than one, the epidemic dies out, and if R_0 is greater than one, the epidemic will grow. This simple model fits many epidemics very well, as shown by the original work of Kermack and McKendrick looking at the 1905–1906 Bombay plague epidemic.

Disease dynamics have become central to some of the most important current questions in population ecology – namely, the relative importance of endogenous (within the system) versus exogenous (outside the system, often called stochastic) forces in determining the dynamics of population. This question, which is central to understanding the importance of any of the interactions outlined in this article, has been dealt with most clearly within the realm of childhood disease (chicken pox, measles, whooping cough, etc.) dynamics because the quality of the data is so good and because the models are more mechanistic.

The data, such as that for measles, have several important features, exhibiting both seasonal behavior driven in part by the school cycle and more complex multi-year cyclic behavior. There have been many different attempts to use extensions of the SIR model to understand the dynamics in a quantitative fashion. The approach taken is essentially to explicitly include the stochastic forces as an integral part of the model and to find the best fit (in a statistical sense) of the model to the data. This procedure illustrates the importance of using these parameter estimation approaches since the standard SIR model with constant infectivity does not provide a very good fit to the data, implying that the model is inadequate in some way. Further investigation shows that making the infectivity seasonally variable, corresponding to the role of school vacations in reducing the likelihood that children infect each other, greatly improves the fit of the model. Moreover, the rather complex dynamical patterns in the disease dynamics are shown to be generated by a combination of exogenous and endogenous forces: both the stochasticity and the nonlinearity (and seasonality) in the SIR model are critical for producing the observed dynamics.

Competition

The simplest models of competition are essentially phenomenologically based and start with the logistic model for a single species as their basis. The effect of each species on the other is to reduce the *per capita* growth rate. From this simple model of competition, several important ecological paradigms have emerged. The basic question to ask is what allows two species to coexist, rather than having a superior competitor eliminating an inferior one. The outcome of competitive interactions ends up being determined, in part, by the relative importance of interspecific effects as compared to intraspecific effects. Coexistence requires that the interspecific effects be weaker than the intraspecific effects.

In contrast to the predator–prey interaction, the dynamics of competition view is a monotonic approach to equilibrium without any cycles. However, if interspecific effects are strong enough, there can be a kind of priority effect. The species that wins in competition may depend on the initial densities in that case.

A more mechanistic approach to competition sheds some light on the issue of coexistence. With interference competition, in which the two species might, for example, affect each other by the production of allelopathic chemicals, interspecific effects may be stronger than the intraspecific ones. With exploitation competition, in which the two species use common resources, the relative strength of interspecific effects and intraspecific effects depends on the differences in resource use – for example, differences in the size of seeds used. From this view comes what was an extraordinarily important principle, the competitive exclusion principle of Gause, which stated that competing species have to differ in order to coexist.

The search for evidence of competition in natural populations is also difficult, but several large-scale surveys have demonstrated that there is relatively good evidence for competition. Classic work in this area includes careful studies of lizards in the Caribbean, which has shown competition for food and avoidance of competition by different species perching at different heights in trees. Competition for space has also been well documented in intertidal systems, in which removal of one species allows another to expand the range of habitat it uses. Recent work has also focused on the apparent competition, in which one species “competes” with another by allowing a common predator to increase its density, which then suppresses the competitor.

Conclusions

Population dynamics is one of the fundamental areas of ecology, forming both the basis for the study of more complex communities and of many applied questions. Understanding population dynamics is the key to understanding the relative importance of competition for resources and predation in structuring ecological communities, which is a central question in ecology.

Population dynamics plays a central role in many approaches to preserving biodiversity, which until now have been primarily focused on a single species approach. The calculation of the intrinsic growth rate of a species from a life table is often the central piece of conservation plans. Similarly, management of natural resources, such as fisheries, depends on population dynamics as a way to determine appropriate management actions.

Glossary

Allele frequency The frequency of a variant form of a genetic locus within a population.

Genetic drift Evolutionary changes caused by random sampling of genotype frequencies in a finite population.

Genotype The state of an individual with respect to a defined genetic locus or set of loci.

Heritability The proportion of the variance in a trait that is due to additive genetic effects.

Inbreeding Matings between close relatives.

Mutation rate The frequency with which new mutations arise per generation.

Neutral mutations Mutations whose effects on fitness are either nonexistent or so small that their fate is controlled by genetic drift rather than by selection.

Phenotype The state of an individual with respect to a trait of interest.

Polymorphism The existence at intermediate frequencies of two or more variants at a locus within a population.

Selection The differential survival or reproductive success of individuals, associated with differences in phenotype or genotype.

Variation Within Populations

Types of Phenotypic Variation

Because evolutionary change depends on the existence of genetic variation within populations, measurement of the extent of such variation is crucial (Lewontin, 1974; Charlesworth and Charlesworth, 2010). Variation at the level of externally visible phenotypes can be divided into three categories.

Discrete Variation

This involves traits that can be divided into a small number of discrete categories, such as eye color in humans or shell color and pattern in the land snail *Cepaea* (Ford, 1975). It is often controlled by one or a few genes, and usually involves relatively superficial traits such as color patterns. Only a relatively small proportion of the phenotypic variation of interest to evolutionists is of this kind.

Quantitative Variation

Quantitative variation is all-pervasive. This can involve either meristic traits, such as bristle number in *Drosophila*, in which there is a large number of discrete categories, or continuously varying metrical traits such as body size. Variation in typical quantitative traits is known to be under the joint control of environmental effects, accidents of development, and sets of genetic variants whose individual effects are small relative to the total range of variation in the traits (Falconer and Mackay, 1996; Flint and Mackay, 2009). Statistical methods that utilize the degree of resemblance between close relatives enable the determination of the proportion of the total phenotypic variation that is contributed by additive genetic causes – the heritability, which controls the rate of response to the selection on a trait (see Selection on Quantitative Traits). Heritabilities for quantitative traits are typically between 20% and 80%, corresponding to the fact that artificial selection is highly effective in changing the mean value of almost every trait that has been examined (Falconer and Mackay, 1996).

Concealed Variability

A more subtle form of phenotypic variation is concealed variability, that is, variability that is only exposed when homozygous genotypes are produced by close inbreeding. This is responsible for the increased variation among inbred lines when a set of such lines is made from a random-bred base population and for inbreeding depression, which is the decline with inbreeding in the mean values of fitness-related traits such as viability and fecundity (Falconer and Mackay, 1996). Both of these phenomena reflect, at least in part, the widespread occurrence of recessive or partially recessive rare alleles in random-mating populations (see Mutation–Selection Balance), whose phenotypic effects are only fully exposed when they are made homozygous and are therefore not evident in randomly mating populations.

In *Drosophila*, special breeding methods, involving the use of genetically marked chromosomes with inversions that suppress crossing over, have shown that most haploid genomes carry at least one recessive lethal gene. Lethals contribute about half of the inbreeding depression in egg-to-adult survival that is manifested when fully homozygous genotypes are produced; a similar reduction in viability is caused by genes of small effect; the net fitness of fully inbred *Drosophila* is only a few percent of that of outbred flies (Crow, 1993). Even more extreme effects of complete inbreeding are likely for vertebrates, which have much larger genomes. The deleterious fitness effects of inbreeding have probably played a major role in promoting the evolution of mechanisms of inbreeding avoidance, such as the self-incompatibility genes of flowering plants (Charlesworth and Charlesworth, 2010).

Interpreting Phenotypic Variation

These basic facts were established by the early 1950s and led to an active debate concerning the causes of natural variation (Lewontin, 1974; Charlesworth and Charlesworth, 2010). From one point of view, championed by H. J. Muller, variation is mostly due to rare deleterious alleles maintained by mutation pressure at a large number of sites in the genome;

the coexistence of alleles at intermediate frequencies (polymorphism) is a rare event. From another point of view, advocated by Theodosius Dobzhansky, polymorphism is the norm, and reflects variation that is actively maintained by selection. In the absence of any means of identifying genes without the prior existence of genetic variability, no unbiased survey of the extent of genetic variation at individual genes was possible with the methods of classical genetics, and so this question could not be answered.

Molecular Variation

Protein Electrophoresis

This situation was transformed by the development of molecular genetics. Gel electrophoresis of soluble enzymes and proteins has provided a rapid and simple method for surveying populations for variants affecting the structure of a large number of different proteins and hence genes (Lewontin, 1974; Charlesworth and Charlesworth, 2010). The results of such surveys reveal that a large fraction of genes coding for soluble proteins are polymorphic, in the sense of having at least one rare variant whose frequency exceeds 5%; the average individual from a randomly mating population is typically heterozygous for a significant fraction (several percent) of such genes. Despite some biases in the methodology, particularly the inability of electrophoresis to detect several types of amino acid sequence changes and the restriction of the method to soluble proteins, it is clear that protein polymorphism is not an exceptional situation.

Measurement of Variation in Nucleotide Sequences

The introduction of sequencing technology has meant that population geneticists can now study variation at the level of the nucleotide sequencing itself. Surveys of within-species DNA sequence variation in nuclear genes of eukaryotes have been intensively carried out in *Drosophila* and humans, but comparable results are emerging from other species (Charlesworth and Charlesworth, 2010; 1000 Genomes Project Consortium, 2010). The basic conclusion is that changes from one base to another at a nucleotide site (single nucleotide polymorphisms (SNPs)) are the most abundant source of variation in natural populations. For nucleotide substitutions in coding sequences that do not change the amino acid sequence ("synonymous substitutions"), and for changes in introns and intergenic sequences, the frequency with which two randomly chosen allelic sequences from a typical *Drosophila* species differ at a given site ("nucleotide site diversity") is approximately 2%. The value is similar for the bacterium *Escherichia coli* and approximately 0.1% in humans (Charlesworth and Charlesworth, 2010). Literally millions of SNPs are present in human and *Drosophila* populations. For most genes, diversity is much lower for nonsynonymous changes, which alter the amino acid sequence. In addition to SNPs, DNA variability is contributed by insertions (including insertions of transposable elements) and deletions of sets of nucleotides; these mostly involve noncoding regions, and some can be many thousands of bases long (Charlesworth and Charlesworth, 2010). Other types of variability include variation in the sizes of microsatellite and minisatellite repeated

sequences, which provide useful genetic markers (Goldstein and Schloetterer, 1999). The density of such repeats, however, is low in relation to the total size of the genome. The total level of variability at the level of DNA sequences is approximately two orders of magnitude greater than that revealed by electrophoresis, because of the high degree of synonymous and noncoding variability compared with nonsynonymous variability.

Interpreting Nucleotide Sequence Variation

Although variation at the level of nucleotide sequences must underlie most heritable phenotypic variation, it has been difficult to relate the two, except for some intensively studied quantitative traits, especially human diseases (Flint and Mackay, 2009). The abundance of variation in both protein and DNA sequences might seem to vindicate Dobzhansky's view of the causes of natural variation. However, it is likely that a good deal of synonymous and noncoding variability is close to neutrality with respect to its effects on fitness (*see* Molecular Evolution and Variation). Nevertheless, there is now abundant evidence that selection also influences variation and evolution in both coding sequences and regulatory noncoding sequences; many methods for detecting selection from its effects on patterns of DNA sequence variation and evolution have been developed (Charlesworth and Charlesworth, 2010), but space does not permit them to be described in detail here. In addition, selection is the major force controlling phenotypic evolution. The effects of deterministic forces such as selection on variation and evolution within populations will thus be considered next.

Deterministic Population Genetics

Allele and Genotype Frequencies

If the focus is on a given nucleotide site, the basic descriptor of the state of a population is the set of frequencies of the four alternative states, A, T, G, and C (ignoring variants that involve insertions or deletions). If recombination within a gene is ignored, we can consider the set of nucleotide sequences observed for a defined region of the genome ("locus") as alternative alleles, whose frequencies characterize the state of the population. Mendelian inheritance implies that this state is not changed in the absence of evolutionary forces (the occurrence of intragenic crossing over and gene conversion at low frequencies means that this is a good approximation rather than an exact description). This is highlighted by the Hardy-Weinberg principle, which states that the frequencies of diploid genotypes in a random mating population at a locus with a set of n alleles with frequencies $p_1, p_2, \dots, p_n$ rapidly reach equilibrium values given by the multinomial expansion of $(p_1 + p_2 + \dots + p_n)^n$. The importance of this result is that it means that existing natural variation is preserved by Mendelian inheritance. This removes Darwin's difficulties over the rapid loss of variation under blending inheritance, which led him to adopt a theory of the inheritance of acquired characteristics for which there is no empirical foundation (Fisher, 1930).

Mutation

Types of Mutations and their Rates

The ultimate source of natural variation is spontaneous mutation, defined as a heritable change in the genetic material. Mutations arise without reference to the adaptive utility of the phenotypic consequences of the change in question. The most abundant mutations are single nucleotide substitutions, but small deletions and insertions due to slippage during DNA replication are relatively common as well (Drake *et al.*, 1998; Charlesworth and Charlesworth, 2010; Lynch, 2010). Insertions of transposable elements, large deletions and duplications, duplications and deletions of entire chromosomes or haploid genomes (aneuploidy and polyploidy), and chromosome rearrangements, such as inversions and translocations, also occur and contribute to the evolutionary changes in genome structure. Rates of spontaneous mutation in organisms with DNA genomes are extremely low, due to the operation of complex enzymatic systems which repair lesions in DNA; the rates of nucleotide changes per site per cell generation in DNA-based microbes are between 1×10^{-10} and 5×10^{-10} . Similar values apply to mutation rates per cell division in multicellular organisms, but the rate per organism generation is over 100 times higher because of the many cell divisions that occur during the production of the germ cells. This yields a mutation rate per nucleotide site per generation of the order of 3×10^{-9} in *Drosophila* and 10^{-8} in humans (Lynch, 2010; 1000 Genomes Project Consortium, 2010). Per locus rates of mutation to alleles with major phenotypic effects are substantially higher – of the order of 10^{-5} per generation – reflecting the large number of nucleotides in the coding and regulatory regions of typical genes. Rates of change in copy numbers in microsatellite and minisatellite loci are generally much higher, however: as much as 10^{-3} per locus per generation in mammals (Goldstein and Schloetterer, 1999). Mutation rates in viruses with RNA genomes are also extremely high, due to their lack of repair mechanisms (Drake *et al.*, 1998).

Evolution under Mutation Pressure

Given the low rate of mutation at the nucleotide level in DNA-based organisms, the time scale of mutational change in the frequencies of the four alternative states at a nucleotide site is very large – of the order of 100 million generations. Mutation pressure at this level is an extremely weak force, easily opposed by other evolutionary factors. For most purposes, therefore, mutation can be regarded simply as a source of new variation, and unimportant for directional evolutionary change (Fisher, 1930). This statement needs to be qualified when the aggregate effects of mutations affecting a particular phenotype are considered; the numbers of loci affecting a single quantitative trait are sufficiently large that increases in variability due to mutation are detectable in stocks that are initially genetically uniform. The rate of increase in variance per generation is typically of the order of 10^{-3} relative to the nongenetic variance for the trait (Falconer and Mackay, 1996). Given that fitness-related traits are affected by many genes, and that most phenotypic changes caused by mutations are harmful to the organism, the mean values of fitness components decline under mutation pressure when selection is

relaxed by experimental manipulations (Crow, 1993; Drake *et al.*, 1998; Charlesworth and Charlesworth, 2010).

Mutation and Selection

These considerations imply that a relatively weak force of selection, far smaller than is measurable experimentally, can prevent the spread of deleterious mutations. This explains the fact that amino acid polymorphisms are usually much less frequent than silent or noncoding polymorphisms. The same observation applies to comparisons of sequences between different species (Kimura, 1983). A very important form of selection is thus purifying selection, whereby deleterious mutations are constantly being eliminated from the population (*see* Mutation–Selection Balance). Similarly, quantitative traits are often subject to stabilizing selection, such that individuals with extreme trait values are less fit than individuals with intermediate values (Falconer and Mackay, 1996). Variability in quantitative traits is maintained in part by a balance between the input of new variation by mutation and its elimination by stabilizing selection (Falconer and Mackay, 1996; Charlesworth and Charlesworth, 2010).

Selection at a Single Locus

The Basic Model

A large body of theory has been developed to describe the action of natural selection on Mendelian variation. In the simplest case, a single locus with a pair of alternative alleles, *A* and *a*, is considered. A randomly mating, infinitely large population is assumed. Ignoring sex differences, the relative values of the fitnesses of the three possible genotypes *AA*, *Aa*, and *aa* in a diploid can be written as 1, $1-hs$, and $1-s$, respectively, where s is the selection coefficient and h is the dominance coefficient. The parameter s measures the strength of selection ($s > 0$, when *A* is favored by selection; $s < 0$, when *A* is disfavored), and h measures the extent to which the fitness of the heterozygote is affected by the presence of *a*. In this section, the fitnesses are assumed to be constant over time.

Fitness in this context is most easily understood in terms of viability selection in a population with discrete generations, where the relative probabilities of the three genotypes surviving from egg to adult are equivalent to the three fitnesses. In general, selection may involve many different aspects of the life history, especially female fecundity and male mating success. More elaborate models have been developed to study these cases, including extensions of the theory to populations with overlapping rather than discrete generations, but the basic conclusions are similar (Ewens, 2004; Charlesworth and Charlesworth, 2010).

If the frequencies of the two alleles in one generation are p and q , respectively, the change in frequency of *A* over one generation is

$$\Delta p = spq\{q + h(1 - 2q)\}/\bar{w} \quad [1a]$$

where $\bar{w} = 1 - 2pqhs - q^2s$ is the population's mean fitness.

An interesting equivalent form, given by Wright, is

$$\Delta p = \frac{1}{2}pq \frac{d \ln \bar{w}}{dp} \quad [1b]$$

Equation [1b] implies that allele frequency change is in the direction of the gradient of mean fitness with respect to allele frequency. A more detailed analysis of the dynamics of a single locus with an arbitrary number of alleles, and arbitrary but constant fitnesses, shows that mean fitness increases monotonically as allele frequencies change, so that stable equilibria in allele frequency space correspond to the local maxima in mean fitness. The graph of mean fitness against allele frequency is known as an “adaptive landscape” (Wright, 1977; Charlesworth and Charlesworth, 2010).

Directional Selection

For the case of a pair of alleles, when $0 \leq h \leq 1$ (so that the fitness of the heterozygote is bounded by the fitnesses of the homozygotes), A is favored by selection when $s > 0$ and will progress to fixation. This case is referred to as directional selection. If A is initially rare so that second-order terms in p can be neglected. Equation [1a] can be approximated by $\Delta p \approx s(1-h)p$. The initial rate of change of the natural logarithm of allele frequency ($\approx \Delta p/p$) is therefore proportional to the fitness difference between the genotypes Aa and aa. This reflects the fact that, with random mating, rare alleles are overwhelmingly carried in heterozygotes (frequency $2pq$) since the frequency of homozygotes (p^2) is negligible. If A is completely recessive, so that $h=1$, eqn [1a] for rare A is approximated by $\Delta p \approx sp^2$, implying that the logarithmic rate of increase in frequency of A is proportional to sp , which tends to zero with decreasing p . This reflects the extreme rarity of the favored homozygotes, and implies that rare recessive alleles are only weakly selected in randomly mating populations (Haldane, 1932; Charlesworth and Charlesworth, 2010).

Survival of Favorable Mutations

The previous conclusion is reinforced by calculations of the probabilities of survival of new mutations. Even in very large populations, a new mutation is likely to be represented initially in only one or a few individuals. Since reproduction is subject to random variation, described by the probability distribution of the numbers of surviving offspring per mated individual, there is a finite chance in each generation that all carriers of a rare mutant gene will fail to transmit it (Fisher, 1930; Haldane, 1932). The chance that a single copy of a new favorable mutation ultimately survives random loss from a large population of constant size is approximately $2s(1-h)$, assuming a Poisson distribution of offspring number (Haldane, 1932; Charlesworth and Charlesworth, 2010). Most favorable mutations are thus likely to be lost from the population of a few generations after they arise; on average, 148 occurrences of a mutation with a heterozygous selective advantage of 1% are needed for a 95% chance that one will survive.

This implies that there is a considerable random element to adaptive evolution at the genetic level. If there are several different loci at which mutations that provide adaptations to a given pressure of selection can occur, it may be a matter of chance which locus actually responds to the selection in a

given population. The same pressure of selection can therefore result in the divergence of isolated populations at the level of the genotype, even if the same phenotype is evolving. The numerous types of genetic variant involved in the adaptation of different human populations to malarial parasites illustrate this principle (Kwiatkowski, 2005; Charlesworth and Charlesworth, 2010).

The formula for survival probability implies that a recessive favorable mutation has a zero chance of survival in an infinite population; calculations based on diffusion theory (see Fixation Probabilities) show that the probability for a randomly mating population of size N in this case is approximately $0.8\sqrt{s/N}$ (Charlesworth and Charlesworth, 2010). This means that recessive autosomal mutations are unlikely to become established by selection in randomly mating populations of even moderate size. As first pointed out by Haldane, it is not an accident that nonrecessive alleles have been established by selection in cases of recent adaptation involving genes of major effect, such as industrial melanism and pesticide resistance, despite the fact that most spontaneous mutations are recessive with respect to their effects on the phenotype (Ford, 1975; Charlesworth and Charlesworth, 2010).

Time Course of Gene Frequency Change

Once a favorable allele rises to a sufficiently high frequency that random loss is unlikely, its progress in a large population can be calculated by integration of the differential equation which approximates eqn [1a] when selection is weak. This procedure yields expressions for the time needed to change allele frequencies by a given amount (Haldane, 1932; Charlesworth and Charlesworth, 2010). These can be used to estimate selection intensities in experimental and natural populations, by comparing observed trajectories of gene frequency change with the theoretical predictions. This method is particularly useful for microbes, which have short generation times and can be grown in very large artificial populations. Selection coefficients of the order of 0.1% can be measured in such microbial experiments (Charlesworth and Charlesworth, 2010).

The results of these calculations show that the time required to cause a given amount of change in gene frequency is inversely proportional to s and depends only logarithmically on the initial frequency of the favorable allele, except when it is recessive. This implies that selection on nonrecessive alleles can cause evolutionary change on a timescale of the order of a few multiples of $1/s$, almost regardless of the initial conditions. Even a very weak force of selection can thus transform a population in a period of time that is negligible in geological terms. This conclusion is historically very important, because it removes many of the objections to natural selection as a potent force in evolution (Fisher, 1930; Haldane, 1932).

Selection on Quantitative Traits

Predicting the Response to Selection

This question can also be considered in relation to the quantitative traits, which are more relevant to phenotypic evolution than the traits controlled by single genes. The standard model of quantitative genetics (which involves

Figure 1 Each cross indicates the location of a point determined by the mean values of the phenotypic values of a pair of potential parents (x axis) and of their progeny (y axis). The straight line is the regression of y on x , whose slope is equal to the heritability. Families that are successful in reproducing are enclosed in the rectangular box.

several simplifying assumptions) implies that the response to selection on a single quantitative trait is governed by the equation

$$R = h^2 S \quad [2]$$

where the selection response, R , is the difference in the mean value between one generation and the next; h^2 is the heritability of the trait (see Quantitative Variation) (there is no connection with the dominance coefficient introduced previously); S is the selection differential, which measures the intensity of directional selection applied to the trait, and is equal to the difference in mean between the parental individuals who have survived selection and the population mean before selection (Figure 1). Given the fact that h^2 is usually substantially greater than zero, this implies that populations can respond rapidly to directional selection on quantitative traits, as is indeed usually found to be the case (Falconer and Mackay, 1996).

Rates of Change Under Selection

In a sexually reproducing population, the ability of genetic recombination to put together new combinations of alleles means that selection can eventually produce genotypes with trait values that far exceed the range of variation that existed in the original population, simply by causing the fixation of alleles that increase trait value and were segregating in the original population. In the absence of new variability created by mutation, the selection response will eventually stop when all favorable alleles have been fixed by selection. Given the evidence for a significant input of new variation by mutation for typical quantitative traits, a relatively gentle pressure of selection in a large population will not fully deplete variation, so that sustained responses to selection are possible (Falconer and Mackay, 1996). The breeder can produce substantial changes in a single trait over less than 100 generations, comparable in magnitude to geologically rapid changes that have taken thousands of generations in nature. It is therefore unlikely that lack of genetic variation is often a serious constraint

on the ability of populations to undergo phenotypic evolution, unless there is intense selection for a novel combination of traits, which cannot immediately be produced by recombination among existing genotypes.

Selection on Multiple Characters

In general, natural selection acts on suites of characters and not on a single trait in isolation. A multivariate generalization of eqn [2] has been derived (Lande, 2000; Charlesworth and Charlesworth, 2010), which is useful for the interpretation of data on selection on multiple traits:

$$\Delta \bar{z} = G \nabla \ln \bar{w} \quad [3]$$

where $\Delta \bar{z}$ is the change per generation in the vector of mean values for the set of traits, $\nabla \ln \bar{w}$ is the gradient vector of log mean fitness with respect to the set of trait means, and G is the matrix of additive genetic variances and covariances among the set of traits. The similarity to eqn [1b] is evident.

Equation [3] shows that, in general, we can only predict the effect of selection on a trait if we know the extent to which it is genetically correlated with other traits that are also the target of selection. Short-term evolutionary changes in a given trait may be due, at least in part, simply to the fact that it covaries with another trait that is the target of selection. However, provided that the G matrix is nonsingular and fitnesses are constant in time, a stable equilibrium state corresponds to a maximum in the surface of mean fitness with respect to the mean trait values, indicating that selection will ultimately bring the population close to the optima with respect to each individual trait, unless there are strong constraints on the correlational structure of genetic variation. This implies that the concept of an adaptive landscape can be applied to quantitative traits (Lande, 2000).

Maintenance of Variation by Selection

The role of selection in preserving variation rather than destroying it, called balancing selection, is now discussed. This form of selection was unknown to Darwin, and its discovery is one of the most important contributions of population genetics.

Heterozygote Advantage

The simplest case is when the heterozygote at a locus with two alleles has a higher fitness than the two homozygotes, which was first investigated by Fisher in 1922. Let the fitnesses of AA and aa relative to Aa be written as $1-s$ and $1-t$; eqn [1b] now yields the result that there is a unique stable equilibrium at which the frequency of A is $p^* = t/(s+t)$, to which the population converges from any starting point other than fixation for A or a (Ewens, 2004; Charlesworth and Charlesworth, 2010). The classic example of heterozygote advantage is the polymorphism for the β -globin variant in humans that causes sickle-cell anemia when homozygous, a disease which is nearly lethal under natural conditions. The maintenance of this allele in human populations subject to severe malarial infections is due to the selective advantage of heterozygous carriers, conferred by their resistance to malaria. Several other human globin gene polymorphisms, as well as many other

human polymorphisms, are maintained by resistance to malaria (Kwiatkowski, 2005).

Frequency-Dependent Selection

Balancing selection can also be caused by negative frequency-dependent selection, in which the relative fitness of a genotype decreases with its frequency in the population. This obviously acts to inhibit the fixation of an allele that may initially have a selective advantage over other alleles when introduced into a population. Genetically controlled resistance to parasitic disease is subject to this form of selection, since the abundance of a parasite decreases as the number of susceptible hosts diminishes, thereby reducing the selective advantage to a host allele that causes resistance to a particular parasite genotype (Charlesworth and Charlesworth, 2010). A similar frequency dependence affects alleles controlling virulence in the parasite population. The genes thought to be involved in disease resistance, such as the major histocompatibility complex (MHC) loci of vertebrates, are often highly polymorphic and segregate for large numbers of alleles; molecular analyses show clear evidence for balancing selection on these loci (*see* Effects of Linkage to Balanced Polymorphisms and Targets of Local Selection). The role of frequency-dependent selection in this case remains to be established, however. Frequency dependence is also inherent in the dynamics of the self-incompatibility loci of flowering plants, which have very high allele numbers (Charlesworth and Charlesworth, 2010). Similarly, Batesian mimicry, in which an edible species mimics a distasteful model, exhibits frequency dependence since a predator is more likely to mistake a rare mimetic form for the model than a common one (Fisher 1930; Ford, 1975; Charlesworth and Charlesworth, 2010). It should be noted that frequency-dependent selection does not necessarily lead to polymorphism; its outcome depends on a delicate balance of the selective parameters, and dynamic complexities such as limit cycles or even chaos are possible. With frequency-dependent selection, maxima in mean fitness do not necessarily correspond to stable equilibria.

Temporal Variation in Fitnesses

Temporal fluctuations in relative fitnesses can also lead to the maintenance of polymorphisms by selection; in the case of two alleles at a locus with random mating, a sufficient condition is that the geometric mean fitness of the heterozygote over generations exceeds that of both homozygotes (Charlesworth and Charlesworth, 2010). Similarly, spatial variation in the direction of selection can maintain variation, even in the absence of heterozygote advantage. This can happen in two ways. The first requires strong density-dependent regulation within different environmental patches, so that the number of adults emerging from a patch is largely independent of the genetic composition of the eggs laid in that patch. In this case, opposing directions of selection in different patches can maintain polymorphism even if there is completely random mating among the patches (Charlesworth and Charlesworth, 2010). Directional selection in opposite directions on alleles in males and females (sexual antagonism) is a special case of this. Second, restricted migration among populations subject to different directions of selection can result in polymorphism within each population, accompanied

by genetic differentiation among populations. Clinal variation in allele frequencies or quantitative trait values results from geographic gradients in selection pressures, coupled with the smoothing effect of migration, as in the case of Bergmann's rule, which states that the mean body sizes of mammal populations increase with higher latitudes (Charlesworth and Charlesworth, 2010).

Meiotic Drive

Antagonism between the effects of selection at different levels may also maintain variation. The best studied cases involve the phenomenon of meiotic drive or segregation distortion, in which one allele (D) at a locus when heterozygous causes the destruction of gametes carrying the alternative allele (d). In animals, this is usually found to occur only in males. Provided that the fertility of Dd males is affected less than linearly by the destruction of the d sperm, D will gain a transmission advantage. It will spread through the population unless there is a countervailing selective disadvantage at the level of individuals. In the best studied cases of this kind, the SD system of *Drosophila melanogaster* and the t-haplotype system of house mice, the primary disadvantage seems to come from sterility of the DD males (Charlesworth and Charlesworth, 2010).

Mutation–Selection Balance

The balance between recurrent mutations to variants that impair the functions of gene products and selection against them is probably a major factor in maintaining genetic variation, given the fact that higher organisms have tens of thousands of genes (Drake *et al.*, 1998; Lynch, 2010). The large number of changes in a coding sequence that can impair the function of a gene product implies that the process of mutation to deleterious alleles at a locus can be regarded as effectively irreversible, provided that the wild-type allele predominates in the population. If the deleterious alleles at a locus are completely recessive, with selection coefficient s and a rate of origination by mutation from wild type of u , their equilibrium frequency in a randomly mating population (assuming that $s \gg u$) is $q^* = \sqrt{u/s}$. Even lethal alleles ($s=1$) can thus reach appreciable frequencies if they are completely recessive; with $u=10^{-5}$, for example, $q^* = 3 \times 10^{-3}$. However, experimental studies of lethal mutations in *Drosophila* show that they usually impair the viability of heterozygotes with wild type by as much as 2%; detrimental alleles with more minor effects (s on the order of a few percent or less) appear to be much less recessive, with mean h values of approximately 0.25 (Crow, 1993). With random mating, the much greater frequency of heterozygotes than mutant homozygotes means that selection on heterozygotes controls the frequencies of mutations; in this case, $q^* = u/(hs)$. The total rate of mutation to lethal mutations per haploid genome in *Drosophila* is approximately 0.01; assuming $hs=0.02$, the mean number of heterozygous lethals per diploid individual is of the order of 1, in agreement with the direct estimate mentioned previously. Evidence from estimates of selection on deleterious non-synonymous mutations found segregating in populations suggests that the mean number of slightly deleterious mutations per individual in humans is of the order of 800, and 10

times higher in *Drosophila* (Charlesworth and Charlesworth, 2010).

Genetic Load

General Considerations

The previous discussion leads to the consideration of the effect of selection on the fitness of the population as a whole; if there is a large amount of variability with respect to loci under selection, it is obvious that the mean fitness of the population must be much less than that of the best genotype. If fitnesses are measured relative to the value for the optimal genotype in the system under consideration, the reduction in fitness below the maximum value of 1 can be conveniently measured by the genetic load, defined as $L = 1 - \bar{w}$. In the case of viability selection, no genotype can have a survival probability greater than 1, so that L provides an upper bound to the probability that a zygote survives to maturity. More generally, L measures the proportion of the population that dies or fails to reproduce as a result of selective differences among genotypes. The effects of multiple loci on mean fitness can be calculated by assuming that different loci act independently, so that the fitness of a multilocus genotype is given by the product of the fitnesses of all the single-locus genotypes which contribute to it. If L_i is the load contributed by the i th locus, the mean fitness with respect to m independent loci, relative to the value for the optimum genotype, is

$$\bar{w} = \prod_{i=1}^m (1 - L_i) \approx \exp - \sum_{i=1}^m L_i \quad [4]$$

Mutational Load

With nonrecessive deleterious alleles maintained by mutation, the load for a single locus at equilibrium is approximated by $2q^*hs = 2u$. The total load is $1 - \exp - U$, where U is the mean number of new deleterious mutations arising in each generation in a diploid individual. Lethal mutations contribute relatively little to this since their total mutation rate is very low, but detrimental mutations have a major effect: Assuming 20,000 genes with a deleterious nonsynonymous mutation rate of 10^{-5} per coding sequence, the mutational load for a mammalian population would be 0.33, a considerable burden of selective loss. An even larger load is probably caused by mutations that affect noncoding sequences of functional importance (Charlesworth and Charlesworth, 2010; Lynch, 2010).

The existence of a large mutational load suggests that there is an adaptive advantage to a reduction in the mutation rate; this can be studied theoretically by calculating the rate of spread of a rare modifier gene that reduces U by a small amount δU . If the modifier recombines freely with autosomal loci subject to mutation and selection, it has a selective advantage of $hs \delta U$. This raises the question of why mutation rates are not closer to zero; this probably reflects the fact that there is a fitness cost to the necessary repair systems so that U is adjusted to a level at which the costs and benefits of increased repair balance each other (Drake et al., 1998).

Segregational Load

Similar calculations can be performed for models of balancing selection, yielding estimates of the segregational load. In the case of heterozygote advantage, the load due to a single locus is $st/(s+t)$ (Charlesworth and Charlesworth, 2010). Equation [4] can be used to determine the segregational load contributed by a large number of polymorphic loci with independent effects. This can be considerable, even if selection is weak. For example, 10,000 loci each with $s=t=0.001$ would yield a mean fitness of only 0.0067. This is so low that only a very high fecundity species would be able to produce the two surviving offspring per adult needed to maintain itself. This implies that either most molecular variation has very slight or no effects on fitness, or that the assumption of multiplicative fitnesses is unrealistic.

An extreme alternative to multiplicative fitnesses is truncation selection. Genotypes at a set of loci are assumed to be ordered with respect to their fitnesses as determined by the multiplicative fitness model; a fixed proportion of the population, containing the set of genotypes with the highest fitnesses, is allowed to survive. This is equivalent to assuming that individuals compete for a limiting resource, and that only the fittest succeed. Under these conditions, a much larger number of loci can be exposed to selection for a given total L than with multiplicative fitnesses, for the same selection intensity per locus. Less extreme forms of departure from multiplicativity can have similar but smaller effects on the total load.

Substitutional Load

Genetic loads also apply to adaptive evolution. Consider the case of a biallelic locus, where A is initially deleterious and held at a low frequency. If there is a change in the environment so that A becomes favored by selection, it will start to increase. However, in any generation before it reaches fixation, the mean fitness of the population will be reduced below its final value of 1 because of the presence of the unfavored allele. There is thus a load associated with the substitution of a by A , reflecting the fact that natural selection cannot instantly transform a population that contains allele a into one which is fixed for A . The sum of the loads for each generation over the course of a gene substitution is Haldane's "cost of selection," C ; if the population size is N , the total number of individuals eliminated by selection is CN . Provided that selection is not too strong, C is proportional to minus the logarithm of the initial frequency of A ; a typical value is 30 (Charlesworth and Charlesworth, 2010).

The effect of changes at multiple loci can be derived as follows: Assume that there is a steady rate of change in the environment so that in each generation K loci start to experience gene substitutions of this kind. K is the rate of gene substitution in the genome as a whole such that after a long period of evolutionary time, T , the population will differ from its ancestral state by KT substitutions. If a gene substitution takes t generations to complete, Kt loci will be segregating in any given generation, each associated with an average load of C/t relative to a population that is fixed for the favorable alleles. The mean fitness under multiplicative fitness, relative to a population that is fixed for favorable alleles at all currently segregating loci, is then given by $(1 - C/t)^{Kt} \approx \exp - CK$.

Data on rates of protein sequence evolution show that K for an average amino acid site in a protein is approximately $1.5 \times 10^{-9} \text{ yr}^{-1}$ in mammals (Kimura, 1983). With 20,000 loci coding for proteins with an average size of 500 amino acids, K for the genome is 0.015. With $C=30$ and assuming one generation per year, the mean fitness is 0.64, implying a load of 0.36. A much higher load would be found if changes in functional noncoding sequences are also taken into account. This finding of a high substitutional load associated with molecular evolution was one of the main motivations for the development of the neutral theory of molecular evolution, which asserts that most evolution at the molecular level is caused by the random sampling of alleles in finite population size, genetic drift, and not by natural selection (Kimura, 1983). The substitutional load can be considerably reduced by modifications to the assumption of multiplicative fitnesses (see this section, above), so that this argument has lost much of its cogency (Ewens, 2004; Charlesworth and Charlesworth, 2010). Nevertheless, there are other reasons to take the neutral theory seriously (see Molecular Evolution and Variation).

Multiple Loci

No Selection

So far, it has tacitly been assumed that evolutionary change involving more than one locus can be modeled by assuming that alleles at different loci are distributed independently of each other in the population and have independent effects on the phenotypes and fitness. Although this may be a good approximation for many purposes, it is necessary to examine the consequences of relaxing these assumptions. Deviations from independence among loci in randomly mating populations can be described by linkage disequilibrium parameters, which measure the extent to which the frequencies of the different multilocus gamete types or “haplotypes” depart from the frequencies expected by randomly combining alleles at different loci. In the simplest case of a pair of loci, each with two alleles (A and a; B and b), there are four haplotypes: AB, Ab, aB, and ab. Let the frequencies of these be x_1, x_2, x_3 , and x_4 . If the allele frequencies at the two loci are p_A and p_B , we can write the haplotype frequencies as $p_A p_B + D$, $p_A(1-p_B) - D$, $(1-p_A)p_B - D$, and $(1-p_A)(1-p_B) + D$, respectively, where D is the coefficient of linkage disequilibrium. It is easily shown that $D = x_1 x_4 - x_2 x_3$. If the frequency of recombination between the two loci is c ($0 \leq c \leq 0.5$), the value of D in the next generation in an infinitely large, randomly mating population with no selection is $D(1-c)$ (Charlesworth and Charlesworth, 2010).

In the absence of evolutionary forces other than recombination, this result implies that the extent of nonrandom association between a pair of loci decays exponentially at a rate that is determined by the frequency of recombination. This result can be generalized to nonrandomly mating populations and to associations among multiple loci (Charlesworth and Charlesworth, 2010). Unless populations are far from equilibrium, departures from linkage equilibrium at a set of loci require the operation of forces tending to generate nonrandom associations between alleles at the different loci. To be effective, their magnitude must be at least of the order of the

recombination frequencies among them. One such force is random genetic drift (see Random Genetic Drift), which can cause randomly generated linkage disequilibrium among loci for which c is of the order of the reciprocal of the population size (Ewens, 2004; Charlesworth and Charlesworth, 2010). DNA sequence surveys of populations of organisms such as *Drosophila* and humans reveal patterns of dependence between D values for pairs of sites and their distance apart on the chromosome that suggest that drift plays an important role in generating nonrandom associations between variants. These associations can be used to locate variants that affect quantitative traits, including human diseases (Flint and Mackay, 2009; 1000 Genomes Project Consortium, 2010).

Selection on Several Loci

Another possible force causing linkage disequilibrium is “epistatic selection,” in which the difference in fitness between genotypes at one locus varies according to the genotypes at the other loci in the system. If the fitness effects of different loci combine additively, there is no epistasis, and it can be shown that polymorphic equilibria under random mating exhibit no linkage disequilibrium (Ewens, 2004; Charlesworth and Charlesworth, 2010). With epistasis, selection tends to preserve haplotypes that contain favorable combinations of alleles, whereas recombination breaks them down. Linkage disequilibrium is not necessarily present if linkage is sufficiently loose in relation to the strength of epistasis. Multiple alternative stable equilibria may occur in multilocus systems, so that the fate of a population can be affected by the initial conditions from which evolution starts. Stable equilibria do not necessarily correspond to the maxima in mean fitness in the space of haplotype frequencies, another violation of the adaptive landscape principle. However, if epistatic selection is weak in relation to the frequency of recombination, populations tend to converge to trajectories where linkage disequilibrium is nearly constant (quasi-linkage equilibrium), and mean fitness increases monotonically at a rate approximately equal to the additive genetic variance in fitness, according to Fisher’s fundamental theorem of natural selection (Ewens, 2004; Charlesworth and Charlesworth, 2010). This has provided a very useful tool for the analysis of the dynamics of multilocus systems (Barton and Turelli, 1991).

Evolution of Close Linkage

There are two biologically important features of systems with strong epistatic selection. First of all, such selection may impose strong constraints on the degree of linkage between polymorphic loci. Suppose that the population is initially segregating for alleles A and a at one locus but is initially fixed for b at a second locus. If a mutation B arises at this locus, which interacts with the alleles at the first locus in such a way that AB is selectively favored but aB is disfavored, B may be unable to invade the population unless c is below some threshold value. Only mutations at loci that are sufficiently closely linked to the first polymorphism in the system will be able to establish subsequent polymorphisms. This process has probably been important in the evolution of some of the classic examples of “supergenes” (systems of very closely linked loci held in strong linkage disequilibrium by selection), such as Batesian mimicry in butterflies (Ford, 1975) and sex

chromosomes (Charlesworth and Charlesworth, 2010). Similarly, if *ab* and *AB* are both fitter than *Ab* and *aB*, a population fixed for *ab* can only evolve a two-locus polymorphism if there is a double mutation to *AB* and if *c* is sufficiently small. This has probably occurred in the evolution of meiotic drive systems, which require combinations of alleles at several loci where each allele on its own is disfavored (Charlesworth and Charlesworth, 2010).

Second, there is a selective advantage to modifier alleles that reduce the frequency of genetic recombination between the two loci, once a two-locus polymorphism has been established. If suitable genetic variation in recombination rates is available, this will eventually lead to very close linkage (Fisher, 1930). This principle has wide generality; analysis of the conditions for spread of rare modifiers of recombination rates has shown that randomly mating populations under epistatic selection generating linkage disequilibrium will always tend to evolve a closer linkage (Charlesworth and Charlesworth, 2010). Since genetic recombination is a near-universal feature of living organisms, this has led to the search for situations that promote rather than repress recombination; these mostly involve forces such as mutation, genetic drift, and environmental change that perturb populations away from their equilibria under selection alone (Charlesworth and Charlesworth, 2010).

Random Genetic Drift

The discovery that random sampling of allele frequencies in finite populations may be a significant factor in evolution is another major contribution of population genetics. This process has two aspects: The first is the tendency for a population of finite size to become genetically uniform, owing to the fact that there is an increasing chance as time passes that all the copies of a gene are descended from a single ancestral allele (Figure 2). The second is the tendency of isolated populations to diverge in allele frequencies over time, since independent trials of a population with the same initial state will arrive at different allele frequencies by chance.

The first process is closely related to the increase in homozygosity that accompanies the inbreeding of close relatives; both are conveniently studied by means of the concept of identity by descent. Two alleles at the same locus drawn from a population are said to be “identical by descent” if they trace their ancestry back to a single ancestral allele. The extent to which a population has progressed toward genetic uniformity can be measured by its inbreeding coefficient, defined as the probability that a pair of randomly sampled alleles are identical by descent from a common ancestral allele (Charlesworth and Charlesworth, 2010). This is always measured with respect to an initial generation, in which all the alleles at a locus are arbitrarily decreed to be nonidentical (Figure 2).

Increase in Homozygosity

The simplest “Wright–Fisher” model of genetic drift assumes a discrete-generation, randomly mating population of *N*

Figure 2 Each row of circles indicates the alleles at a locus present in a given generation. The distinct copies present in the initial generation are labeled 1–6. The arrows indicate the successful transmission of an allele to the next generation.

hermaphroditic individuals with no selective differences among genotypes at the locus under consideration. New individuals are formed by random sampling (with replacement) of gametes produced by the parents. With diploid inheritance, such that there are $2N$ gene copies at a locus among the breeding adults, the following recursion relation for f_t , the inbreeding coefficient in generation t , is obtained:

$$1 - f_t = \left(1 - \frac{1}{2N}\right)(1 - f_{t-1}) \quad [5]$$

This follows from the fact that the probability that a pair of randomly sampled alleles are both derived from the same allele in the previous generation is $1/(2N)$, in which case they are identical by descent. The probability that they come from two different alleles is $1 - 1/(2N)$; their probability of identity is then f_{t-1} .

Equation [5] shows that f_t tends asymptotically to 1; if N is moderately large, $1 - f_t$ decays exponentially with a half-life of $1.4N$ generations. This result can be generalized to more realistic types of breeding system by means of the concept of the inbreeding effective population size (N_e) (Charlesworth and Charlesworth, 2010). This utilizes the fact that genetic drift in these more general cases can be described by matrix equations or higher-order difference equations, such that a constant rate of decay of $1 - f_t$ is reached asymptotically, yielding an expression of the same form as eqn [5]. The asymptotic decay constant can be equated to $1 - 1/(2N_e)$. For example, a population with N_f breeding females and N_m males has $N_e = 4N_f N_m / (N_f + N_m)$ if there is purely random variation among individuals in their offspring number. In general, N_e is less than the census number of breeding individuals, often considerably so (Charlesworth and Charlesworth, 2010).

Differentiation of Populations

The effect of drift in causing genetic differentiation among populations is described by the variance in allele frequencies among the set of populations in question. In the Wright–Fisher model, the sampling of allele frequencies at a neutral biallelic locus with alleles A and a and frequencies p and q will generate a binomial distribution of the new frequency of A, with mean p and variance $pq/(2N)$. Repetition of this sampling process results in a probability distribution of allele frequencies with steadily increasing variance (Charlesworth and Charlesworth, 2010). The variance of allele frequency, σ_p^2 , can be related to the inbreeding coefficient as follows: Assume that we have a large set of completely isolated populations, all founded with the same initial frequency, p_0 . At some arbitrary time, the set of populations will have a mean gene frequency p_0 (since drift does not change the mean) and variance σ_p^2 . If N is reasonably large, the genotype frequencies within each given population will be in Hardy–Weinberg equilibrium; the mean frequencies of AA, Aa, and aa over the set of populations are equal to $p_0^2 + \sigma_p^2$, $2(p_0q_0 - \sigma_p^2)$, and $q_0^2 + \sigma_p^2$, respectively.

This is the “Wahlund effect”: Genotype frequencies averaged over a set of populations that are each in Hardy–Weinberg proportions show an excess of homozygotes and a deficiency of heterozygotes compared with Hardy–Weinberg expectation, the magnitude of which is determined by the variance in gene frequencies among the populations. This is a purely algebraic result, independent of the causes of the variation. It can be related as follows to the effects of genetic drift in causing increased homozygosity. Assume that a diploid individual is formed by sampling two random alleles from the same population. The probability that the alleles are identical by descent is f ; they are then both A in state with probability p_0 . The probability that they are nonidentical is $1-f$, in which case the probability that the two alleles are both A is p_0^2 . The net probability that the individual is AA is thus $fp_0 + (1-f)p_0^2 = p_0^2 + fp_0q_0$. Comparison with the previous expression shows that

$$\sigma_p^2 = fp_0q_0 \quad [6]$$

This establishes that the variance in allele frequency is proportional to the inbreeding coefficient under the Wright–Fisher model, and so its change over time is governed by eqn [5]. This is often but not always true under more general models of population structure, with N_e replacing N in the binomial formula for the variance conditional on the current gene frequency. In some circumstances, particularly when the population size changes with time, the conditional variance in allele frequency requires a different denominator in order to be represented by the binomial formula. In this case, a “variance effective population size” is computed (Ewens, 2004; Charlesworth and Charlesworth, 2010).

Molecular Evolution and Variation

The Neutral Theory

These simple models of genetic drift can readily be applied to the study of molecular evolution and variation, assuming selective neutrality at the loci in question. Neutral theory allows for the possibility that many mutations are subject to

purifying selection and are rapidly eliminated from the population (see Fixation Probabilities); it is claimed, however, that the fate of most mutations that are not removed by purifying selection is determined by drift rather than by selection (Kimura, 1983). This theory constitutes a useful null hypothesis, which can be tested against data on molecular evolution and variation by means of predictions of several different types.

Rate of Neutral Evolution

Consider first the rate of molecular evolution as measured by the rate of substitution of mutations, K (see Substitutional Load). In a population of N breeding adults, there are $2N$ allele copies at an autosomal locus. As shown in the section Increase in Homozygosity, eqn [5] implies that the population tends to homozygosity with probability of 1. This means that the remote descendants of the current population will all trace their ancestry back to just one of these $2N$ alleles. Under neutrality, the probability that a given allele is the ancestor is thus $1/(2N)$. It follows that the probability of fixation of a new neutral mutation in a population of size N is $1/(2N)$; the probability that it is lost is $1 - 1/(2N)$. If the rate of mutation to neutral variants is u per generation, the expected number of new mutations that enter the population is $2Nu$, of which only $1/(2N)$ are destined for ultimate fixation; the expected number of mutations that ultimately become fixed is $2Nu/(2N) = u$.

If the process of mutation and drift has reached a stationary state, so that the expected number of new substitutions is equal to the number of substitutions that reach completion in each generation, we obtain the fundamental equation of neutral molecular evolution:

$$K = u \quad [7]$$

This relation holds for any level in the genetic hierarchy, from the nucleotide site through the locus to the genome as a whole, provided that K and u are defined appropriately. Since K can be determined by comparisons of DNA sequences among species with known divergence time (see Substitutional Load), and u values are known from genetic studies, eqn [7] can be used to test the neutral theory.

One prediction is that genomic regions whose sequences are essentially functionless, such as pseudogenes, should evolve at the mutation rate, since they are necessarily unconstrained by selection. If adaptive Darwinian evolution is a minor factor in molecular evolution, the rate for sites in these regions should be much higher than that for functionally significant regions, where selection is expected to eliminate most of the mutations (see eqn [10] below). These regions do indeed evolve at similar rates to those expected from mutation rate estimates, and other regions evolve more slowly (Kimura, 1983; Charlesworth and Charlesworth, 2010). This does not, however, rule out a role for selection in fixing advantageous variants in selectively constrained regions; it could still be true, for example, that most nonsynonymous mutations (see Measurement of Variation in Nucleotide Sequences) are deleterious or neutral, but a minority are advantageous rather than neutral, so that the changes that are fixed in evolution are adaptive rather than neutral. There are also some exceptional cases of higher rates of nonsynonymous

versus synonymous substitutions in coding regions; this is a strong evidence for a positive role of selection on the amino acid sequences concerned (Charlesworth and Charlesworth, 2010).

Another prediction of eqn [7] is that the rate of molecular evolution should be constant over long periods of time, since it depends only on the mutation rate. In contrast, the rate of evolution under natural selection is expected to be highly variable, because the theory described earlier (*see* Selection on Quantitative Traits) suggests that populations will tend to adapt quickly to a new environment (or go extinct), after which change will be slow or nonexistent. This is borne out by the observations of comparative biology and paleontology, which show that evolution at the external phenotypic level is generally highly episodic and triggered by ecological opportunities such as the occupation of vacant niches. Studies of DNA and protein sequence evolution suggest that the rate of evolution of a given molecule is much less variable among different lineages, or within the same lineage at different times, than is true for the external phenotype, especially when noncoding or silent substitutions are considered (Kimura, 1983; Charlesworth and Charlesworth, 2010). This has generated the concept of a “molecular clock,” which is used to estimate the times of divergence of taxa when paleontological data are absent. However, there is evidence for more variability in rates of evolution than predicted by the simplest form of the neutral theory, especially for amino acid sequences. This suggests a role for selection, although the interpretation of such rate variability is controversial (Charlesworth and Charlesworth, 2010).

Neutral Polymorphism

The process of fixation of neutral variants is a slow one; calculations based on diffusion theory (*see* Diffusion Equations) show that the mean time for fixation of a new neutral mutation in a random mating population (conditioned on ultimate fixation) is approximately $4N_e$ generations, during which the variant on its way to fixation causes a polymorphism. Variability is also contributed by the large fraction of new mutations that are destined for ultimate loss. In the neutral theory, polymorphism is simply a phase of molecular evolution. Although there is a constantly shifting set of variants at any one locus, the mean amount of variability can be determined by assuming a statistical equilibrium between drift and mutation, using the following argument (Kimura, 1983; Charlesworth and Charlesworth, 2010).

The simplest version of this applies to a single locus, which is assumed to have no recombination. Thus, there are many possible sequences; new neutral mutations are assumed to occur with probability u per generation, and each mutation represents a sequence that has not been observed before. This is the “infinite alleles” model. Let h_t be the probability that two randomly sampled alleles are distinct in sequence in generation t . An argument similar to that leading to eqn [5] shows that, after neglecting terms in $u/(2N)$, h_t for a Wright–Fisher population obeys the equation

$$h_t \approx \left(1 - \frac{1}{2N}\right)h_{t-1} + 2u(1 - h_{t-1}) \quad [8a]$$

At equilibrium, rearrangement of this equation yields the relation

$$h \approx \frac{4Nu}{4Nu + 1} \quad [8b]$$

More generally, N_e can be substituted for N in eqn [8b]. The parameter $\theta = 4N_e u$ thus controls the equilibrium level of variability under the neutral model. A large amount of neutral variability can be maintained, provided θ is sufficiently large, for example, with $N_e = 10^5$ and $u = 2 \times 10^{-7}$, $\theta = 0.08$, and $h = 0.074$. This value of h is similar to the mean per locus heterozygosity for electrophoretic alleles in mammalian populations (Lewontin, 1974; Kimura, 1983).

This model can be modified to predict the equilibrium level of diversity per nucleotide site by assuming that the units of observation are the individual sites, not the entire locus. If it is assumed that θ is much less than 1, so that at most one variant is segregating in the population at each site, eqn [8b] can be applied to yield the equilibrium value of π , the nucleotide site diversity (*see* Measurement of Variation in Nucleotide Sequences), such that π is approximately equal to θ . This is Kimura’s “infinite sites” model, which is widely used in the interpretation of data on molecular variation.

The Coalescent Process

General Considerations

The growing body of data on DNA sequence variation within populations has stimulated interest in the development of statistical tests for the agreement of the observed patterns of variation with the predictions of the neutral theory. To conduct such tests, it is essential to have predictions concerning the properties of statistics describing samples of alleles from populations and not merely of properties of the populations from which the samples are drawn, since these cannot be observed directly. A powerful method for deriving the properties of samples has been developed, known as coalescent theory (Ewens, 2004; Wakeley, 2008; Charlesworth and Charlesworth, 2010). It is based on the following principle. Consider a pair of alleles at an autosomal locus sampled from a Wright–Fisher population. As shown in the section Increase in Homozygosity, there is a probability $1/(2N)$ that they are derived from a common ancestral allele in the previous generation, that is, they “coalesce.” If they fail to coalesce, which has probability $1 - 1/(2N)$, they have a probability $1/(2N)$ of coalescing in the next generation back, and so on.

There is thus a geometric distribution of the time back to the common ancestral allele, such that the probability of time t is $(1/2N)(1 - 1/[2N])^{t-1}$. From the well-known properties of this distribution, the mean time back to the common ancestor is close to $2N$ and the variance is approximately $(2N)^2$. Assume that mutations occur at the rate u per site in the gene, such that each mutation that arises in the line back to descent connecting the two sampled alleles is at a different site (the infinite sites assumption, *see* Neutral Polymorphism). If there are m nucleotide sites in the sequence in question, the number of mutations conditioned on t has a mean and variance of $2tmu$ since the total time separating the alleles is $2t$, and the conditional number of mutations follows a Poisson

distribution. The mean and variance of the number of differences between the two alleles are then $m\theta$ and $m\theta + (m\theta)^2$, respectively. The result for the mean corresponds to that derived from eqn [8b] since the nucleotide site diversity is simply the number of differences between the pair of alleles divided by m , and the mean of t is equal to $2N$.

This can be extended to a sample of n alleles from a population. If N is sufficiently large, the chance of more than one coalescent event per generation can be neglected. There are $n(n-1)/2$ possible pairwise allelic combinations, so that the probability of a coalescent event is $n(n-1)/(4N)$. The time to the first coalescent event is therefore distributed geometrically, with a mean of approximately $4N/(n[n-1])$, and the variance is approximately equal to the square of the mean. The time from this to the next coalescent is also geometrically distributed, replacing n with $n-1$, and so on. The process can be represented by a genealogical tree, whose nodes with k and $k-1$ alleles are separated by a time tk that is geometrically distributed with mean of $2/(k[k-1])$ on the coalescent timescale of $2N$ generations (Figure 3). As previously mentioned (see Increase in Homozygosity), N_e replaces N for more general models of breeding structure. The rate of coalescence evidently diminishes as the number of nodes decreases.

This representation can be used to derive many important results, and it also provides a rapid means of simulating genetic processes, since time can be rescaled to the coalescent timescale and the properties of a sample of alleles represented by generating genealogical trees from samples drawn from the

relevant distributions, with mutations scattered randomly over the branches of the tree. The expected pairwise difference between all $n(n-1)/2$ pairs of alleles on the infinite sites assumption is readily seen to be $m\theta$. Its variance is also known (Ewens 2004; Wakeley, 2008; Charlesworth and Charlesworth, 2010). This statistic provides the obvious means of estimating the nucleotide site diversity in the population (π) by equating the observed mean pairwise difference to its expectation. However, another statistic, the total number of segregating sites in a sample of n alleles (S_n), has better statistical properties under the infinite sites model. These can be obtained as follows: The total size of a tree is the sum of kt_k over the entire tree. Application of the above formulae for mean coalescent times with different numbers of alleles shows that the expectation of the tree size in units of coalescent time is simply $A = 2 \left(1 + \frac{1}{2} + \frac{1}{3} + \dots + \frac{1}{(n-1)} \right)$. The number of sites in the sample that are segregating for nucleotide variants is the number of mutations that appear on the tree. Its expectation is $2N\mu A = m\theta A/2$; θ can therefore be estimated by dividing S_n by $mA/2$. The variance of this estimator is substantially lower than that based on pairwise diversity.

Tests of Neutrality

Several tests for departures from neutrality have been devised based on the properties of the coalescent process (Ewens 2004; Wakeley, 2008; Charlesworth and Charlesworth, 2010). One widely used method is Tajima's D test, which uses the fact that departures from neutral equilibrium have different effects on the pairwise difference estimate of θ and on the estimate of S_n . For example, a population bottleneck of reduced size that completely removes variability at a locus will be followed by a long period of recovery, during which new mutations are all at low frequencies. This means that the pairwise diversity, which is weighted by the frequencies of variants, will be much lower in relation to the observed number of segregating sites than in an equilibrium population, reflecting the fact that the genealogical tree is like a "star phylogeny" in this case (Figure 3). Purifying selection on the variants in question will have a similar but much smaller effect. The opposite pattern is expected if there has been a partial bottleneck, in which rare variants have been lost from the population, or if variation is affected by balancing selection. The Tajima test computes the ratio of the difference between the two estimates of θ to its standard deviation (calculated using the neutral equilibrium model), and compares the result with critical values obtained from coalescent simulations. Other tests have been devised using similar principles (Ewens, 2004; Wakeley, 2008; Charlesworth and Charlesworth, 2010).

Interaction of Drift with Deterministic Forces

Population Subdivision

General Considerations

One important complication of the neutral theory is population subdivision; species in nature are not simple randomly mating populations but instead are usually distributed over wide geographic areas, with limited migration between localities. Random genetic drift can thus produce significant genetic

Figure 3 Two types of gene genealogies. (a) The genealogy of a set of alleles in a population of constant size. The tips of the tree represent six alleles sampled from the population. Each node corresponds to a coalescent event. Each cross line represents a new mutation in the DNA sequence of the gene in question, which has arisen since the common ancestor of the sample; mutations in internal branches of the tree give rise to at least two variants in the sample. (b) The genealogy of a set of three alleles in a population that experienced a recent reduction in size to one allele, followed by rapid expansion with no opportunity for coalescent events.

differentiation among local populations if migration is sufficiently restricted. This creates two problems: How to describe data on allele or nucleotide site variant frequencies when there is differentiation among populations, and how to relate models of the underlying evolutionary processes to the data?

Partitioning Variability

The basic method used to summarize data collected from a set of populations sampled from the same species is to partition variability into a within-population component that describes the mean level of variability within a sample, and a between-population component that measures the mean difference between alleles sampled from different populations. This can be done either using data on allele frequencies, as in the case of electrophoretic loci or microsatellite loci, or using nucleotide site variant frequencies. In many cases, it is also possible to organize the populations sampled into a hierarchy of decreasing geographic scale, such as subspecies within a species, races within subspecies, and local populations within races. Variability can then be partitioned into variation between and within each level of the hierarchy (Charlesworth and Charlesworth, 2010). A frequent practice is to normalize each lower level measure of between-population variability relative to variability at the next higher level of the hierarchy, generating a set of Wright's F statistics or the related G statistics of Nei (Charlesworth and Charlesworth, 2010).

The procedures will be illustrated here for the case of DNA sequence variation in a population divided into a set of equal-ranking subpopulations. The total nucleotide site diversity, π_T , is defined as the fraction of nucleotides that differ between a pair of alleles drawn randomly from the set of samples as a whole. The within-population nucleotide site diversity, π_S , is the mean fraction that differs between a pair of alleles drawn from the same subpopulation. The amount of between-population differentiation can be measured by the between-population component of nucleotide site diversity, $\pi_{T-S} = \pi_T - \pi_S$. A normalized measure of differentiation is defined as $K_{ST} = \pi_{T-S} / \pi_S$.

The Island Model

Although the previously mentioned measures of population differentiation are useful as descriptive tools, they can also be used to estimate the evolutionary parameters that determine the extent of population differentiation. This requires the development of models of the joint effects of genetic drift, mutation, and migration, one of the most complex problems in theoretical population genetics. The simplest and most widely used model is the island model, which assumes that the species is divided into d distinct subpopulations or "demes," which each behaves according to the Wright–Fisher model with population size N . After reproduction has occurred within each deme, a fraction m of each deme's genes are replaced with genes drawn randomly from the other $d-1$ demes. Coalescent theory can be used to determine the mean coalescence times of pairs of alleles sampled from the same population (t_0) or from different populations (t_1); it is found that $t_0 = 2Nd$ and $t_1 = 2Nd(1 + [d-1]/[4Ndm])$ (Wakeley, 2008; Charlesworth and Charlesworth, 2010). In the infinite sites model, the mean fraction of nucleotides that differ between a pair of alleles is equal to the product of the mutation

rate per site and twice their coalescence time (see The Coalescent Process) so that the expected number of nucleotide site differences between alleles can be derived directly from the corresponding coalescence times.

An important and somewhat counterintuitive conclusion is that the within-population nucleotide site diversity, π_S , is equal to $4Ndu$, that is, it depends on the total number of individuals in the set of populations in the same way as the diversity in a panmictic population under the infinite sites model, and it is independent of the migration rate (with the proviso that $m > 0$). As expected, the other diversity measures depend inversely on Nm , with large between-population divergence being possible only when $Nm < 1$; for large d , K_{ST} is approximately equal to $1/(1 + 4Nm)$. Values of these statistics that are close to zero are generally taken to indicate relatively little population differentiation, whereas values close to one imply considerable differences among local populations relative to the within-population variability.

Other Models of Population Structure

Although simple to analyze, the island model is not very realistic biologically since dispersal is limited in most species, so that local populations are most likely to acquire immigrants from nearby. Attempts to generate useful results from more realistic models have taken two directions. The first involves maintaining the assumption of a set of discrete demes but allowing for differences in deme sizes. Migration is described by a migration matrix M , such that m_{ij} is the probability that an allele currently in deme i originated in deme j in the previous generation. However, it is difficult to obtain transparent general results for such a model. Under the infinite sites model, however, the result that $\pi_S = 4Ndu$ still holds if migration is conservative, that is, migration does not change the sizes of local populations (Wakeley, 2008; Charlesworth and Charlesworth, 2010). Simple analytical results on genetic diversity within and between populations are only available for special cases, such as the stepping-stone model, in which demes of size N in a linear or planar array receive migrants with probability m only from immediately adjacent populations (Wakeley, 2008; Charlesworth and Charlesworth, 2010). This model also permits the analysis of the dependence of degree of genetic differentiation between populations on the distance between them. The results show that extensive differentiation between populations is possible with a one-dimensional array of populations, even if there is a considerable amount of migration, whereas the results for a two-dimensional array are similar to those for the island model.

The second approach assumes that individuals are distributed over a one- or two-dimensional spatial continuum, with density ρ . Migration is represented by the probability density that an individual moves a given distance between birth and reproduction. If migration follows a random walk, the variance of the migration function, σ^2 , is sufficient to describe the process. This is Wright's isolation-by-distance model. A mathematically correct formulation of this model presents formidable difficulties, but it is possible to obtain useful approximate results (Charlesworth and Charlesworth, 2010).

Effects of Directional Selection at Linked Loci

Another complication in interpreting data on DNA sequence variation is that even neutral variation may be affected by selection at the linked sites. The classic example is hitchhiking, where a new favorable mutation arises as a unique event and spreads throughout the population. In the absence of recombination, variants at linked loci will be dragged to fixation as the favorable allele sweeps through the population so that variability at these loci is eliminated. With recombination, the magnitude of this hitchhiking effect decreases with the ratio of the frequency of recombination between the selected and neutral locus (c) to the selection coefficient (s) at the selected locus, and it is negligible when this ratio is of the order of 1 or more (Charlesworth and Charlesworth, 2010). The effects of hitchhiking by favorable mutations are thus only likely to be manifest at sites that are closely linked to the target of selection. There are many examples of the detection of such hitchhiking events in natural and human populations (Charlesworth and Charlesworth, 2010).

However, hitchhiking effects can also be caused by deleterious mutations, a process termed background selection (Charlesworth and Charlesworth, 2010). A neutral variant which is tightly linked to a deleterious mutation that is in the process of elimination from the population will have a high chance of being eliminated before it can unhitch itself by recombination. As discussed previously (*see* Mutation–Selection Balance), the genomes of higher organisms contain many loci subject to mutation to deleterious alleles; therefore, relatively small individual effects of selection against mutations at single loci may have a large cumulative effect on neutral variability.

Studies of genetic variation in *Drosophila* and some other species have shown a strong relationship between the amount of recombination in the region where a gene is located and the level of genetic variation that it exhibits (Charlesworth and Charlesworth, 2010). Similarly, species or populations of hermaphroditic organisms with high rates of self-fertilization, in which the absence of heterozygotes means that genetic recombination is effectively absent, also seem to show reduced levels of molecular variation. In human populations, variability at the noncoding sites that are closer to genes is lower than sites situated far away from genes. Both hitchhiking by favorable mutations and background selection can account for these patterns, and current research is attempting to distinguish between them.

Effects of Linkage to Balanced Polymorphisms and Targets of Local Selection

Selection at linked sites can also cause increased variability at the neutral sites if selection is balancing rather than directional in nature. This can be understood in terms of a single locus with two alleles, A and a, maintained by strong balancing selection in a randomly mating population. This means that the population is effectively divided into two subpopulations represented by the two allelic classes. If the two alleles are equally frequent, a neutral site linked to this locus with recombination frequency c has a probability $0.5c$ of crossing over from one subpopulation to the other; this is equivalent to the migration rate m in the case of an island model with just two

islands. This leads to an expansion of the coalescent time at the neutral site by a factor of $1 + 1/(4N_e c)$, where N_e is the effective population size. This implies that the maintenance of variability by selection is accompanied by a corresponding increase in nucleotide site diversity at the sites that are very closely linked to the target of selection, as seen at the MHC loci in mammals (Charlesworth and Charlesworth, 2010).

Increases in neutral variation among subpopulations of a species may also occur at sites linked to loci subject to local selection, causing large among-population differences in allele frequencies. Variation in the behavior of neutral variability along a chromosomal region can thus provide valuable evidence on the action of spatial differences in selection pressure, and genome-wide scans for signatures of these effects in human populations have been carried out with considerable success (Charlesworth and Charlesworth, 2010; Hancock *et al.*, 2010).

Diffusion Equations

General Considerations

A full treatment of genetic drift must deal with properties other than summary statistics of allele frequency distributions of the type considered so far, particularly if selection is to be studied. The difficulties involved in exact analytical treatments of the properties of genotype frequency distributions are great, so resort is usually made to approximations involving the use of diffusion equations, which treat genotype frequencies and time as continuous variables and assume that all the evolutionary forces are sufficiently weak that second-order terms in their effects on frequencies are negligible. The standard approach is to assume a single biallelic locus. Using the continuity assumptions, the state of the population can be described by either of the following two partial differential equations, writing $\phi(x, p, t)$ for the probability density of the frequency, x , of allele A at time t , given an initial frequency p :

$$\frac{\partial \phi}{\partial t} = \frac{1}{2} \frac{\partial^2 (\phi V_{\delta x})}{\partial x^2} - \frac{\partial (\phi M_{\delta x})}{\partial x} \quad [9a]$$

and

$$\frac{\partial \phi}{\partial t} = \frac{V_{\delta p}}{2} \frac{\partial^2 \phi}{\partial p^2} + M_{\delta p} \frac{\partial \phi}{\partial p} \quad [9b]$$

where $M_{\delta x}$ is the expected change in gene frequency and $V_{\delta x}$ is the variance of the change in gene frequency, both conditioned on x . $M_{\delta x}$ can be equated to the change in gene frequency in an infinite population; under random sampling of allele frequencies, $V_{\delta x}$ is approximated by $x(1-x)/(2N_e)$.

Equation [9a] is the forward Kolmogorov equation and eqn [9b] is the backward Kolmogorov equation (Ewens, 2004; Charlesworth and Charlesworth, 2010). Multidimensional versions of these equations describe systems with multiple alleles and multiple loci but are usually difficult to analyze.

Stationary Distributions

Equation [9a] is useful for describing the probability density function for an allele frequency. However, even for the simple case of a biallelic locus, a full general solution of this equation

to yield the density as a function of time has been obtained only for some special cases. It is most useful for studying the properties of stationary distributions of gene frequency, when drift comes into statistical equilibrium with mutation, migration, and selection (Ewens, 2004; Charlesworth and Charlesworth, 2010).

The study of such distributions has led to some important conclusions, most notably that selection is highly effective at countering the effects of drift in a randomly mating population when $N_e|s|$ is >1 but is ineffective when $N_e|s|$ is <1 , where $|s|$ is the magnitude of the selection coefficient defined in the section The Basic Model. When the first condition holds, there is little scatter around the mode of the gene frequency distribution; when the second condition holds, there is a high probability that the population is close to fixation, or fixed, for the disfavored allele. If $N_e|s|$ is of the order of 1, both drift and selection are considered to be significant forces.

Fixation Probabilities

The previous conclusion can also be derived by consideration of the probability of fixation of an allele A with initial frequency p , $P(p)$, for which a general formula was found by Kimura using the backward equation (Kimura, 1983; Ewens, 2004; Charlesworth and Charlesworth, 2010). With intermediate dominance, such that $h=0.5$ in eqn [1a], and assuming that a single copy of the mutation is present initially ($p=1/[2N]$), this formula simplifies as follows:

$$P\left(\frac{1}{2N}\right) = \frac{1 - \exp\left(-\frac{N}{N_e}s\right)}{1 - \exp(-2N_es)} \quad [10]$$

For a selectively favorable allele, with $s>0$, the fixation probability tends to $(N/N_e)s$ as N_e tends to infinity. When $N_e=N$ (as in the Wright–Fisher model), this is equivalent to the branching process result for the survival probability of a favorable mutation in a very large population (*see* Survival of Favorable Mutations). The asymptote is approached when $N_es>1$, so that a selection coefficient larger than $1/N_e$ is sufficient to ensure that a new favorable mutation behaves as though the population is infinite. Conversely, a selection coefficient of this size against a deleterious mutation ($s<0$) means that it is almost certain to be eliminated from the population.

These considerations led Fisher (1930) to conclude that random genetic drift is unlikely to be effective as an evolutionary force on the grounds that (1) most species have numbers of breeding individuals at least in the tens of thousands, and usually in the hundreds of thousands or even millions, and (2) it is unlikely that a gene would have such a small effect on the phenotype that its average effect on fitness over evolutionary time would be of the order of 10^{-4} or less. Although a compelling argument with regard to genetic changes that affect the phenotype, this view has been challenged by the neutral theory of molecular evolution.

As already noted, the causes of protein sequence evolution are still controversial, but studies of the statistical properties of between- and within-species patterns of silent substitutions at the third coding positions support the idea that these are affected by both drift and selection in bacteria, yeast, and *Drosophila*. There is not only a tendency for certain triplets

that code for the same amino acid to be favored by selection, but there is also evidence that this selection is so weak that disfavored nucleotide changes can drift to fixation within a species. Estimates of the intensity of selection can be obtained by comparing the observed distributions of frequencies of synonymous nucleotide variants with those predicted by solutions of the diffusion equations, and suggest that N_es for preferred codons is typically approximately 0.5 in *Drosophila* (Charlesworth and Charlesworth, 2010).

Hill–Robertson Interference

Selection may become ineffective if recombination is restricted among the loci subject to selection, because of linkage disequilibrium generated by random genetic drift (Hill–Robertson interference: Charlesworth and Charlesworth, 2010). There are several different processes of this kind, but all involve the key feature that selection at one site in the genome impedes the action of selection at another genetically linked site. This is because a finite population does not contain all possible combinations of variants that can be produced by mutation. If mutations (either favorable or deleterious) arise in different individuals, a favorable variant at one site will generally be present in a genotype with a deleterious variant at other sites, that is, there is negative linkage disequilibrium between selectively favorable variants. As recombination breaks down linkage disequilibrium, it enhances the population's ability to respond to selection. The selective sweep and background selection processes mentioned in the section Effects of Directional Selection at Linked Loci above are in fact examples of Hill–Robertson interference where the variants concerned are not all under some form of selection.

The background selection model assumes the continual occurrence of mutations that are sufficiently deleterious that their expected frequencies remain close to their low equilibrium values in an infinite population. In nonrecombining genomes or genomic regions, however, deleterious mutations will not necessarily behave like this, but instead may accumulate; this process is called Muller's ratchet. Consider, for example, the case of a haploid asexual population in which mutations occur exclusively from wild-type to deleterious alleles but not in the opposite direction (*see* Mutation–Selection Balance), and where $N_es \gg 1$. If the selective effects of mutations at different loci are identical, a population can be characterized by the frequencies of genomes containing 0, 1, 2 ... mutations. If the frequency of the mutational class containing the lowest number of mutations (the least-loaded class) is sufficiently small, it will be lost from the population after a finite number of generations. Given the assumed irreversible nature of mutation and the lack of opportunity for genetic recombination, the least-loaded class cannot be reconstituted and will be replaced by the class with one more mutation. This class is now vulnerable to stochastic loss in the same way. There is thus a repetitive process of loss of successive least-loaded classes, in which the loss of each class can be regarded as a turn of Muller's ratchet. The speed of the ratchet depends in a complex way on the effective population size, the number of individuals in the least-loaded class in an equilibrium population, and the strength of selection

(Charlesworth and Charlesworth, 2010). If it does operate, there will be an approximately exponential decline in the mean fitness of the population.

In the results previously discussed, which suggest that individuals in equilibrium sexual populations carry many hundreds or thousands of deleterious mutations, even a very large asexual population of a higher organism is likely to be vulnerable to the operation of the ratchet and other forms of Hill–Robertson interference, probably leading to its eventual extinction. Asexual prokaryotes, with their much smaller genomes and enormous population sizes, are less likely to suffer this fate. This may account for the fact that very few species of higher organisms, with their large genomes, are asexual or lack recombination, whereas prokaryotes and mitochondria often have very low levels of recombination. It may also contribute to the loss of most ancestrally functional genes from Y chromosomes (Charlesworth and Charlesworth, 2010).

Group Selection

Another situation where the supremacy of individual selection can be overcome occurs when species are subdivided into local populations, among which migration is so restricted in relation to the reciprocal of local population size that drift can overcome its homogenizing influence (*see* Population Subdivision). An allele that is deleterious within its local population may drift to fixation locally in opposition to selection, since N_e for the local population is much smaller than for the species as a whole. This creates the opportunity for group or interdeme selection. If the allele in question causes its carriers to be altruistic, in the sense of conferring increased fitness on the members of their deme at the expense of suffering a loss in fitness to themselves, demes in which the allele reaches high frequency or fixation will achieve a higher mean fitness. This may render them less susceptible to extinction, or more able to contribute to the pool of migrants or to find new demes. Selection among demes can therefore result in the spread of an allele that causes a reduction in individual fitness but benefits the population as a whole (Haldane, 1932; Charlesworth and Charlesworth, 2010).

Although this is a theoretically viable mechanism, there are reasons to doubt that it is widely applicable to evolution in nature, since it requires high levels of genetic differentiation between local, as well as the appropriate balance of selective effects at the individual and group level. Studies of molecular genetic variation within and among populations indicate that many species lack extensive differentiation among local populations (*see* Partitioning Variability), suggesting that migration is often so effective that the necessary conditions for group selection are not met.

Kin Selection

Most examples of altruistic behavior, such as the sterility of the worker castes in social insects, are generally believed to be the result of kin selection rather than group selection. An altruistic genotype that aids relatives may experience a selective advantage, even in a large, randomly mating population, if the

fitness benefit b to the recipients of the altruism is sufficiently large in relation to the cost c to the altruists (Haldane, 1932; Charlesworth and Charlesworth, 2010). This is because the genetic similarity of related individuals means that the relatives of an altruist have a greater chance than average of carrying an allele that promotes altruism; according to “Hamilton’s rule,” there will be an increase in the frequency of an altruistic allele when $b r > c$, where r is a measure of the relatedness of the altruists to the recipients. There is an extensive theoretical literature on the correct way to calculate r under different conditions, and the theory of kin selection has played an important role in the evolutionary interpretation of social behavior and the sex ratio.

The Shifting Balance Theory

A process that is very similar to group selection for altruism is the shifting balance theory of evolution (Wright, 1977; Charlesworth and Charlesworth, 2010). Wright postulated that epistatic interactions in fitness among alleles at different loci are widespread, resulting in multiple stable equilibria under selection. The simplest case is a haploid two-locus, two-allele model, with ab and AB both fitter than Ab and aB . Fixation for ab or AB is stable against introduction of Ab and aB , whereas fixation for Ab or aB is unstable to the introduction of ab and AB . With constant fitnesses and loose linkage, locally stable equilibria are approximated by the peaks in the surface of mean fitness as a function of the allele frequencies at the loci concerned (*see* The Basic Model). A population will approach the peak that is the nearest attractor rather than the highest peak in the landscape. Genetic drift can cause a local population to travel down the adaptive valley separating the current equilibrium to the zone of attraction of a neighboring peak, and selection can then bring it to the new equilibrium. If this is associated with a higher mean fitness than the surrounding peaks, the process of interdeme selection can cause the species as a whole to acquire the genotype associated with this peak, and hence improve in mean fitness.

In contrast to the group selection model of altruism, the new equilibrium is dynamically stable under individual selection. This process has the attractive feature that it allows the species to acquire an adaptively superior genotype or character combination that would otherwise require multiple simultaneous mutations. Its drawback is that it requires a delicate balance among restricted migration, local population size, and the nature and intensity of selection to operate with any frequency. It is difficult to distinguish the end products of the shifting balance process from ordinary individual selection, which does not have such stringent requirements, and it remains unclear whether it has played an important role in adaptive evolution (Charlesworth and Charlesworth, 2010).

Conclusions

This article has necessarily omitted many important topics. It has focused on the basic general principles governing evolutionary change in populations; space did not permit more than a brief mention of the application of these principles to

wider biological problems, including life history evolution, the evolution of genetic and sexual systems, the evolution of social behavior, speciation, and the interpretation of macro-evolution. Very little useful can be said about natural variation and evolution at almost any level without taking population genetic concepts into account.

Glossary

Stochasticity A stochastic process is one in which the state of the system cannot be precisely predicted given its current state, even with a full knowledge of all the factors affecting that process. In a population context, we may know the detailed life history parameters of a species. However, various unpredictable (stochastic) processes, such as the chance nature of birth and death (demographic stochasticity), year-to-year variation in climate (environmental stochasticity), and catastrophes, means that accurately predicting the precise size of a population in the future is not possible. Despite this, we can use probability theory and simulation models to make probabilistic predictions. A stochastic population model is one in which each possible future population size has an associated probability. This approach to prediction is the same as stating that the chance of getting a head with the next toss

of a fair coin is 50%. While our prediction is accurate, we cannot say if the outcome will be a head or a tail.

Viability (and related concepts) A viable population is one deemed to have a reasonable chance of long-term persistence. Such a definition begs two questions: What is reasonable and what is long-term? It has been stated that a viable population is one that has a 99% chance of persisting 1000 years. Different managers, researchers, and policymakers use different measures that range from a 99% chance of persisting 1000 years to a 95% chance of persisting 100 years. The population size that just meets the definition of being viable is called a minimum viable population (MVP). One of the key questions of reserve design is how big does a reserve, or network of reserves, need to be to contain an MVP. This size is called a minimum viable habitat area for a particular species.

What is Population Viability Analysis (PVA)?

Traditionally, PVA is a process in which a stochastic population model is used to assess the viability of a population. The population may be a species, subspecies, metapopulation, or an isolated subpopulation of a single species. Classical PVA uses a demographic population model to derive a result such as: "given current circumstances the probability of extinction of species *X* over the next *Y* years is *Z*%." For example, in his seminal 1981 paper, Shaffer used a demographic population model to determine the probability of extinction of grizzly bears, *Ursus arctos*, in Yellowstone National Park within the next 100 years (Shaffer, 1981).

Most PVAs use a demographic population simulation model that incorporates all the processes likely to affect the dynamics of the population. PVA differs from other population modeling exercises in its focus on predicting the probability of extinction and the inclusion, typically, of stochastic processes that are believed to have a strong impact on the probability of extinction. For convenience, the authors categorize these stochastic processes into four types; each can be thought of as a way in which variability influences the dynamics of a species. Given that these processes are central to our thinking about PVA, they are described in detail. In a broader context PVA can be thought of as just one branch of the larger field of population modeling, but with a primary focus on an assessment of risk. Risk is the probability of an unfavorable event; in this case the unfavorable event is the extinction of a species or a population falling below a threshold level.

PVA is unique in the context of conservation biology because it assesses the adequacy of conservation efforts. Given an

acceptable risk of extinction for any species, then, in theory we should be able to manage every species so that its extinction risk does not exceed this acceptable level. If we can do this, our conservation strategy would be deemed "adequate."

During the past decade, the authors have realized that the simple view of PVA as a process that uses a demographic simulation model to assess extinction risk is too narrow. First, the restriction of PVA to the use of demographic population modeling software ignores other tools for assessing viability. We now view PVA as a broader process that includes various sorts of theory, analytic and computer modeling, and forms of data analysis (Boyce, 1992; Beissinger and Westphal, 1998). Second, despite our inability to assess accurately the extinction probability of most populations, PVA can be used to make robust management decisions. The broader roles of PVA are explored later. It is this management-based approach to PVA that is now broadly accepted and considered practically useful.

Stochastic Population Processes and Extinction

Types of Demographic Population Fluctuation

Demographic Stochasticity

Demographic stochasticity is the chance nature of birth and death. It causes populations to fluctuate because populations are composed of individuals that are units (Kendall and Fox, 2003). Each unit counts as one and is born and dies as a unit, so populations can only increase and decrease on the set of integers. Each individual has a probability of dying and a probability, each year, of finding a mate and producing

offspring. The dynamics of five separate populations, fluctuating as a result of demographic stochasticity alone, are shown in Figure 1.

Each population has its own trajectory even though they all have the same life history parameters and started from the same population size. In a sense, demographic stochasticity is the most fundamental phenomenon that causes populations to fluctuate because it occurs in all populations. In Figure 1 each population should, on average, increase 5% per year, but one becomes extinct after 15 years and another increases to more than 40 individuals. The importance of demographic stochasticity for extinction and PVA diminishes in larger populations because the minor “wobbles” caused by the

unitary nature of birth and death are overshadowed by the more dramatic environmental stochasticity and catastrophes (Figure 2).

A rarely discussed type of demographic stochasticity is the chance nature of sexual determination in organisms with more than one sex. For example, a population may be known to have six individuals, which may appear to have some chance of persisting if conditions are good. However, there is a 1 in 32 chance that all the individuals are the same sex and the population is doomed if each has an equal chance of being male or female. When populations are small, a skewed sex ratio can have a major impact on the chance of extinction.

Figure 1 Five sample trajectories for a population in which demographic stochasticity is operating. For each individual, each year there is a 30% chance of dying. Those that survive have a 50% chance of giving birth to one more individual. Despite identical conditions the populations diverge rapidly, with one becoming extinct after 15 years and another increasing to more than 40 individuals. With these parameters, in the absence of stochasticity, the population should on average increase at a rate of 5% (0.7×1.5) per year.

Figure 2 The impact of environmental stochasticity on the dynamics of five populations. For trajectory A, the parameters are the same as those used for Figure 1 with just demographic stochasticity, except the population started with 100 animals. Note the fairly consistent increase of about 5% per year with minor fluctuations caused by demographic stochasticity. For the other four populations, the death rate is not fixed at 30% but varies randomly between 20 and 40% from year to year. Also, the probability of producing an offspring is not fixed at 50% but varies from 40 to 60% from year to year for the whole population. Note the much wider fluctuations in population size, even when the populations are larger than 100. Also note the differences between the trajectories and dynamics even though the parameters are the same on average – the consequence of stochasticity.

Environmental Stochasticity

As biotic and abiotic conditions vary from year to year, there will be variation from year to year in vital rates. This sort of variation tends to affect the entire population; therefore, there are years in which breeding success may be good or bad. Because this variation tends to operate on the entire population, it causes more dramatic fluctuations in population size (Figure 2).

Catastrophes

Some natural events cause precipitous declines in the sizes of populations, such as fire, flood, disease, and frost. Although these events can be seen as an extreme form of environmental variation, they are often considered separately as catastrophes. The authors define a catastrophe as being a single event that causes the death of a substantial fraction of a population. Recent analysis implicated catastrophes in the extinction, or near extinction, of many species. The Puerto Rican parrot was almost wiped out by a hurricane, the Guadeloupe oriole by a volcanic eruption, black-footed ferrets by canine distemper, and a population of heath hen by fire. Species with populations that are spatially restricted, such as those on islands, are particularly vulnerable to catastrophes. However, disease appears to be able to decimate continental populations over huge areas. Disease is implicated as a factor contributing to declines of once common species, such as the passenger pigeon and many Australian carnivorous marsupials such as the Tasmanian tiger. Figure 3 shows the trajectory of four populations for which there is a 2% annual probability of 90% of the individuals being killed in a single catastrophe.

Including catastrophes is an important part of any PVA (Mangel and Tier, 1993) but a difficult component to include in models because of limited data on the frequency and impact of catastrophes. Although we often have good data on catastrophes such as fire, and these have been successfully included in models of Australian forest fauna (Lindenmayer and Possingham, 1996), we rarely have good data on

catastrophes such as disease that are more difficult to detect but probably just as important.

Genetic Stochastic Processes

Genetic stochastic processes change the frequencies of genes within a population. When a population is small and isolated, genetic variation is typically lost from generation to generation. This process is called genetic drift. As frequencies of alleles change at random with each successive generation, genetic variability is reduced because rarer alleles are lost by chance through the stochastic nature of birth and death. Inbreeding is defined as mating between individuals that are related by ancestry and is more likely in populations that are, or have been, small. Inbred animals can have reduced survival, fecundity and growth (inbreeding depression). Inbreeding expression can be expressed in particular environmental conditions such as harsh winters. Inbreeding depression results in the selective removal of inbred animals and the genes carried by such animals (Lacy, 1993). Morphological defects in threatened species such as the Florida panther (*Felis concolor coryi*) and lack of breeding success in the Puerto Rican parrot (*Amazona vittata*) appear to be a result of inbreeding depression. The restoration of genetic variability is slow and believed to be between 1 and 10×10^{-6} genes per generation per 100 years. Thus, genetic mutations have only a minor effect in reversing the loss of genetic variation during the time frame typical for PVA. A longer term consequence of loss of genetic variability is a reduced ability of a population to adapt to environmental changes.

Overview of the Role of Stochasticity on Time to Extinction

Each kind of stochasticity has quite distinct effects on the relationship between extinction probability and population size (or carrying capacity). Analytic and simulation studies have shown that although the mean time to extinction, and hence the viability of a population, grows nonlinearly with

Figure 3 The impact of catastrophes on the dynamics of four populations. The same parameters as in Figure 2 are used and include both demographic and environmental stochasticity. However, there is a 2% chance per year that 90% of the population dies. These catastrophes cause enormous fluctuations in the population sizes that can take very healthy large populations to the brink of extinction whereupon demographic and environmental stochasticity are sufficient to cause extinction.

population carrying capacity when only demographic stochasticity is operating, the other two forms of stochasticity can make even large single populations quite vulnerable to extinction (**Figure 4**). With only demographic stochasticity the mean time to extinction increases very rapidly above species-specific thresholds (usually approximately 50–100 individuals). Therefore, in the absence of environmental variability, catastrophes, and genetic stochastic processes, quite small populations could persist for very long times. Adding environmental variation means that the benefits of increasing population size are diminished and there are no simple thresholds above which populations are likely to be completely secure. Because catastrophes can reduce a population to a small size very quickly, a larger population size brings diminishing returns in terms of viability (Lande, 1993). When this occurs, the best way to improve population viability may be to ensure that a single catastrophe cannot affect the whole population – a risk-spreading approach. This issue will be discussed later.

Deterministic Extinction Processes and Extinction Vortices

A major contribution of PVA to conservation biology is that it focuses attention on stochastic extinction processes in small populations. This should not distract our attention from equally important, more deterministic processes that lead to extinction (Caughley, 1994). Habitat loss and associated fragmentation, increases in mortality rates from introduced predators, and reduced reproduction through habitat modification all have significant impacts on the carrying capacity and rates of increase of populations. Although the distinction between deterministic and stochastic extinction processes is useful conceptually, it is worth noting most important impacts on species have deterministic and stochastic components.

The deterministic and stochastic extinction forces need to be integrated. We can think of the interaction of some of these processes as extinction vortices, in which they nonadditively contribute to the demise of a species. For example, a

Figure 4 The three different types of population stochasticity have different impacts on the relationship between the mean time to extinction and the size (or carrying capacity) of a population.

catastrophe may take a population close to extinction, resulting in a period of inbreeding depression, which keeps the population sufficiently low so that demographic stochasticity finally causes extinction. Another example is the way in which habitat loss causes population fragmentation where each isolated population is small enough to fall victim to the interaction of genetic and demographic stochastic processes (Gilpin and Soule, 1986).

Understanding the process of extinction is fundamental to our ability to model it. The obvious question arises: What use is an extinction model?

Why do Population Viability Analysis?

Applications of PVA

Originally, PVA had two general purposes. Shaffer's (1981) original intent was to assess the viability of a population. This assessment of extinction risk is useful in that it informs us of the effectiveness of conservation strategies. In the case of the grizzly bear in the Yellowstone region of the United States, the assessment implied that the species was unlikely to persist in the long term. In the following years, PVAs were tied very closely to the idea of a MVP. Scientists and managers used PVA to determine if the strategies for conserving a population were adequate. The goal was to use PVA to derive a target population that was large enough to be viable and then to recover the species to that level as quickly as possible.

When one of the primary tools for managing a threatened species includes setting aside an area of suitable habitat for that species, the idea of an MVP extends to that of a minimum viable habitat area (MVHA). An MVHA is a useful concept in which the main threatening process is habitat destruction. However, it has limited value when threats to a species are not simply removed by reservation, such as the continued activities of a predator (e.g., the western swamp tortoise in Western Australia). An MVHA can be predicted using a PVA by predicting extinction probabilities as a function of reserve area. Typically, the relationship between extinction probability and area conserved is sigmoidal (**Figure 5**). The MVHA is simply derived by choosing an acceptable level of extinction probability and then conserving the corresponding area. In some cases, the possibility that a single habitat patch ensures viability is unlikely because of catastrophic events, and PVA models that allow for multiple populations (metapopulations) are necessary to determine an adequate reservation strategy. Such a strategy depends on the number, size, and spatial distribution of reserves and the nature of the catastrophic events.

Another application of PVA that relies on the accurate assessment of extinction probability for a species is assembling lists of threatened species. Many countries and states are required, for legislative and resource allocation purposes, to maintain and update lists of threatened species. The International Union for the Conservation of Nature has explicit definitions of the different categories of threatened species: critically endangered, endangered, vulnerable, rare, insufficiently known, and extinct (Mace and Lande, 1991). These criteria are becoming increasingly complex and they vary from

Figure 5 The relationship between old-growth patch size and extinction probability of Leadbeater's possum (Lindenmayer and Possingham, 1996) for high-quality habitat in the absence of any catastrophes. Reserves less than 20 ha are of almost no value in isolation, whereas reserves of 100 ha have considerable resilience to demographic and environmental stochasticity. When there are fires that destroy the entire patch, there is no single patch size that gives an acceptably low extinction probability.

country to country. One means of classifying species according to their level of threat would be to do a PVA on every species in the list. Although this has the merits of apparent objectivity, PVAs are rarely used for classifying threatened species because there are insufficient data to parameterize PVAs for so many species. One approach to dealing with the uncertainty associated with extinction probabilities is to take a decision analysis, or fuzzy set, approach in which each species is allocated a probability of being in a particular threatened species category (Akçakaya *et al.*, 2000).

In the United States, the ideas of MVPs, MVHAs, and species classifications are given a litigious dimension because of the federal Endangered Species Act. The Endangered Species Act and associated recovery plans and habitat conservation plans state that any development should not compromise the viability of an endangered species. Some other countries have followed suit. The idea of habitat conservation planning is to allow development where parties agree to the level of mitigation necessary to ensure viability. Because the notion of viability is central to this law and the planning processes that have arisen from the law, PVA has entered the courts in land-management and planning disputes (Bingham and Noon, 1997).

Population Viability Analysis for Making Management Decisions

During the 1990s, scientists questioned the traditional uses of PVA and also questioned the ability of PVA to accurately predict extinction risk for most species (Possingham *et al.*, 1993; Taylor, 1995; Beissinger and Westphal, 1998). Workers have found that the probability of extinction of an organism is very sensitive to small variations in key life history parameters, especially adult mortality rates. There appears to be adequate data to make very accurate estimates of extinction risk for only a very small fraction of threatened species.

An alternative role for PVA is as a decision support tool to help make management decisions. This role focuses on the

robustness of different management decisions to deliver acceptable conservation strategies rather than the accuracy of the predictions alone (McCarthy *et al.*, 2003; Baxter *et al.*, 2006). PVA can be used to make decisions regarding the following: (1) Determining if, and how much of, a population should be brought in to captivity; (2) Translocation strategies between populations or to new sites; (3) Reintroduction strategies (Armstrong and Seddon, 2008); (4) Deciding how to set priorities between species; (5) Determining optimal habitat management, including disturbance regimes such as fire and logging; (6) Control strategies for the predators, competitors, and prey of threatened species; (7) Optimal size, distribution, and spatial pattern of reserve systems.

Probably the most widespread and frequent application of PVA is through the activities of the Captive Breeding Specialist Group (CBSG). This group aids zoos and conservation agencies throughout the world to set conservation priorities and actions by work-shopping species groups region by region. Some argue that PVA has been most useful in providing a framework within which experts can operate. The task of running a PVA draws the experts together and focuses their attention on estimating population dynamics and identifying threats. This is certainly true for the CBSG workshops and users must view PVA as a decision support tool and not as the decision maker.

Other Measures of Viability

The probability of extinction of a population is not the only measure of population viability. Other common measures are the mean and median of the time to extinction. When the extinction probability for a species is fairly constant, the expected life span of the species can be thought of as being negatively exponentially distributed so the rate of extinction is simply the inverse of the mean time to extinction (Grimm and Wissel, 2004). All these measures are fairly closely related.

Because of the uncertainties associated with modeling the dynamics of very small populations (Allee effects, genetic effects, etc.), one prudent approach to providing a measure of risk is to introduce the notion of quasiextinction, which is the risk of the population decreasing in number to some preset size. For example, although the probability of extinction is the chance of decreasing to zero individuals, a manager may argue that the conservation of a species has failed long before this and prefer to set a threshold population size of, for example, 20, below which the population is quasiextinct. This approach eliminates some of the problems associated with modeling very small populations.

An even more general approach to assessing extinction risk that extends the idea of quasiextinction is to develop risk curves. A risk curve (Figure 6) shows the probability of a population decreasing below any population size, from zero (extinction) to the carrying capacity of the population. With a risk curve, the manager is free to pick whichever quasiextinction threshold he or she wishes, or to assess alternative management strategies by investigating changes in the whole risk curve. A quasiextinction risk curve can be summarized by the average distance from extinction, which is equal to the expected minimum population size.

Figure 6 Hypothetical risk curves. The user can choose whatever combination of threshold population size and level of risk he or she wishes. The four lines are quasiextinction risk curves for different levels of population harvesting.

Methods and Tools for Population Viability Analysis

Demographic Models for Population Viability Analysis

Generally, a PVA is a demographic model that includes some or all of the extinction processes discussed previously. There are several ways of constructing these models, and there are several publicly available software packages that people can use to do PVA. The general categories of PVA model are discussed in the following sections.

Matrix Population Models

Basic demographic projection is one of the most powerful and important parts of PVA, although sometimes it is bypassed. By constructing an age- or stage-structured population projection matrix, one can determine both the overall growth rate of the population and the sensitivity of that growth rate to variation in life history parameters by finding the dominant eigenvalue of the matrix. More simply, the population can be projected forward in time using a simple spreadsheet. If the dominant eigenvalue of the population is less than one then we know the population is doomed to extinction (deterministic extinction). If there is uncertainty about the value of key life history parameters, then the risk of deterministic extinction can be calculated by carrying out a sensitivity analysis on the dominant eigenvalue. Although this approach does not allow for any of the stochastic forces described previously, it gives the manager an idea of how the population is faring in the absence of stochasticity. If the dominant eigenvalue is likely to be less than one, then our sensitivity analysis allows us to target those life history attributes, such as birth rate or adult death rate, most likely to generate a positive long-term growth rate. Matrix population models can include stochasticity (indeed, RAMAS Age is based on the application of projection matrices for its predictions), but without a computer package the mathematics is quite complex.

Analytic Methods and Approximations

Although including stochasticity normally requires that we proceed to a computer simulation, there are analytic methods for calculating the probability of extinction, and in particular

the mean time to extinction, of populations. One approach uses Markov chain theory to model a basic birth and death process. This model includes only birth and death and can be used to generate analytic expressions for the mean time to extinction.

Another analytic approach involves approximating the stochastic population dynamics with differential equations called “diffusion” equations. Diffusion equations can be analyzed to generate explicit expressions for the mean time to extinction of a population under different sorts of stochasticity; indeed, this approach was used to generate the relationships shown in [Figure 4](#).

Although analytic approaches have elegance and generality, they are restricted in the processes which can be included and they can be quite difficult to parameterize from field data. They have made significant contributions to our general appreciation of the role of stochasticity in extinction and underpin a general theory of extinction, but they are rarely used in practice.

Time Series Analysis Methods

A relatively new method for exploring extinction risks utilizes analysis of time series of population abundance. During the past decade, a considerable amount of time series data on a wide variety of organisms have been obtained. If these time series of population size are sufficiently long (at least 15 years), then it is possible to statistically “fit” different models of stochastic population growth (such as a Ricker model or logistic model) to these time series. Such models are necessarily simple but have the advantage that they do not require any life history data – only a series of counts. Given the best fit model, it is a straightforward task to simulate the dynamics into the future and calculate extinction risks ([Morris and Doak, 2002](#)).

Although this approach will prove increasingly useful for making extinction risk predictions, and hence helping with tasks such as prioritizing species, the lack of mechanisms in these models limits their application for management purposes.

Numerical Methods

The approach of using a Markov chain (or stochastic population projection matrix) can be expanded to include other forms of stochasticity besides simply demographic. If transitions from any population state to any other population state can be estimated as a function of life history attributes and biotic and abiotic influences, then increasing these matrices to increasingly higher powers allows us to project the probability distribution of possible population sizes into the future. This method provides the foundation of the RAMAS extinction risk software.

The numerical method has the advantage of some mathematical elegance, and it is certainly powerful when coupled to front-end software such as that available in RAMAS. However, most people who build models from scratch find the mathematics involved too complex and tend to use the Monte Carlo simulation method.

Monte Carlo Simulation Models

The most common way of doing PVA is to use a Monte Carlo simulation model. These simulation models are either written

from scratch or the user uses one of the available packages (Lindenmayer *et al.*, 1995). The most frequently used packages are VORTEX and RAMAS (several versions/types); however, others are available. The basic structures of all these models are fairly consistent and are best visualized in a flow chart (Figure 7). However, the details of how each component is modeled and which processes can be included in the models vary considerably from model to model and species to species. Each has its strengths and weaknesses. For detailed application to a particular species it is advisable, although expensive and time-consuming, to construct models specific to that species that focus on relevant processes and management options.

For example, several different kinds of PVA models were built to determine efficient and adequate conservation strategies for the northern spotted owl (*Strix occidentalis caurina*). These ranged from simple demographic models to very detailed landscape models with habitat dynamics and very specific biological factors such as predation by another owl. The diversity and number of models for this species largely reflect the controversy regarding it: The spotted owl requires large tracts of forested land that are very valuable for timber production. For species that have far less economic importance, there is neither the time nor the money to embark on detailed modeling exercises and so one of the existing packages is used.

Monte Carlo simulation models run on a PC have the advantage that they can incorporate many different parameters and processes; their complexity is limited only by the

imaginings of the biologists and managers. However, the inclusion of detail and complexity can give the illusion of accuracy, whereas some consider that adding more poorly understood processes will make the results less accurate. The factors driving the extinction estimates from complex models are often very difficult to isolate.

Sensitivity Analysis of Population Viability Analysis Models

Sensitivity analysis is an important component of modeling because one can use it to systematically investigate the complex interactions of a model. Sensitivity is usually measured by varying a parameter by a small amount from its estimated value. The resulting change in the state variable (e.g., the risk of extinction) provides an index of the sensitivity of the model to that parameter. Sensitivity analysis provides practical information for model builders and users by highlighting parameters that have the greatest influence on the results of the model. It can highlight model parameters that should be most accurately measured so as to maximize the precision of the model, give a general indication of the reliability of the model predictions, and highlight parameters and interactions that have the largest influence on the population to help determine effective management strategies.

The sensitivity of deterministic matrix population models can be determined analytically by eigen-analysis. Extension of these techniques to PVA is not appropriate for most PVA models except for matrix models for at least three reasons: (1) PVA models are often complex, so obtaining solutions analytically is difficult if not impossible; (2) in PVA, the result of interest is the risk of population decline and not the deterministic growth rate; and (3) interactions between variables are largely ignored.

Any method of sensitivity analysis should be clearly defined, interactions between parameters should be distinguishable from single parameter effects, and the method should account for variability associated with parameter estimates. The simplest approach to sensitivity analysis of PVA models is to vary the model parameters in turn and investigate the effect on the risk of population decline. Alternatively, such a sensitivity analysis can determine whether the relative efficacy of different management decisions changes with different parameter values. PVA models may be complex with numerous parameters, particularly when individuals are modeled, and understanding the relative importance of different parameters and interactions between parameters may be difficult. For example, if there are 10 parameters and three levels for each parameter are to be investigated, then 21 different parameter combinations would be necessary to assess each parameter independently. However, 3^{10} (= 59,049) different combinations are required to test all possible interactions.

When the risk of population decline is the important state variable, logistic regression may be useful for summarizing the effects of different parameters and interactions. Data for the regression are generated by using numerous parameter combinations. For each parameter combination, the PVA model is simulated to obtain a limited number of predictions of the incidence of decline. The regression analysis uses the model parameters as explanatory variables and the incidence of

Figure 7 A flow chart showing the typical processes included in a Monte Carlo simulation PVA.

decline as the dependent variable. The regression equation provides a simple expression to approximate how the probability of decline is influenced by the model parameters.

Problematic Issues in Population Viability Analysis Models

Although all models of populations are necessarily false because they cannot include all the factors and processes that influence population dynamics, we believe that some processes and factors in PVA modeling are important but are difficult to incorporate.

Genetics in Population Viability Analysis Models

Early work on PVA paid considerable attention to the role of genetics, although the significance of genetics in short-term threatened species management has declined (Lande, 1988). Two genetic issues are of particular concern: inbreeding depression and loss of heterozygosity. Inbreeding depression is of particular concern for very small populations, especially captive populations. Estimating the likelihood and effect of inbreeding depression on vital rates is problematic. The loss of genetic heterozygosity is a long-term concern. Populations with an effective size greater than 50, are generally thought to experience low losses of heterozygosity. VORTEX is a generally available package that allows the user to include genetic factors, hence its popularity with zoos and reintroduction programs.

Genetic data can be difficult and expensive to obtain and one needs to consider how the data will influence one's decision making. A useful role of molecular genetic data in PVA is to provide estimates and plausible bounds for demographic attributes that are otherwise impossible to obtain (such as social structure and dispersal rates).

Density Dependence in Population Viability Analysis Models

Density dependence at both low and high densities is important for PVA. At low densities the possible consequences of positive (or negative) density dependence are critical to the ability of a species to recover. For populations with limited habitat, the way in which vital rates change as populations approach their carrying capacity, and whether the carrying capacity fluctuates greatly from year to year, is known to influence estimates of viability. Unfortunately, information on density-dependent processes for most threatened species is extremely limited. Different PVA models use different forms of density dependence, from logistic growth and a population "cap" to no density dependence, whereas other models allow the user to choose the appropriate form.

Space in Population Viability Analysis models: Metapopulation Models and Risk Spreading

Space is an essential component of any PVA model for which the intention is to make statements about what management actions should take place at which particular geographic locations. For example, in determining habitat reconstruction plans for threatened species (linking corridors and new habitat patches), it is generally essential to represent space explicitly in the models.

Space can be incorporated into a PVA model either implicitly or explicitly. The implicit use of space is typical of many metapopulation models in which the interest is in the number of patches that are occupied, with no particular regard to exactly which patches are occupied. These models can be used in a general sense to report on the values of different reserve sizes or corridors. For detailed management for which the question of exactly where a corridor needs to be located, or which patch needs to be protected, might need to be answered, we normally require models in which real landscapes are explicitly represented.

Habitat Dynamics

Early PVA models, and almost all of the analytic approaches, assume a static habitat. Given that habitat loss is one of the primary causes of species extinction, the introduction of habitat dynamics in PVA models is of increasing interest. Even in the absence of habitat loss, most habitats are dynamics and some recent PVAs have focused as much on the dynamics of the landscape as on the dynamics of the population. This reflects an increasing interest in population ecology – not just in the role of space but also in the role of a changing habitat mosaic in population dynamics.

Combining habitat dynamics with spatial complexity has been facilitated by faster computers and increasing use of geographic information system (GIS) software. Future wildlife managers will certainly have access to GIS systems that enable them to interactively explore the consequences of different habitat management actions on extinction probabilities. These complex new-age GIS/PVA tools will include the tools inherent in GIS systems, habitat suitability models, management models, stochastic catastrophes, and detailed population dynamics (Akçakaya *et al.*, 2004). To some this will be a powerful and compelling tool and to others a dangerous cascade of complex untested models interacting in ways that the user will never understand.

Other Methods of Assessing Viability

There are many measures of viability and many ways of assessing viability – from a wild guess to a complex computer model, and from a simple analytic model to extrapolation from empirical data. So far, the authors have discussed more traditional model-based methods. Here, the authors briefly mention two other ways of assessing the viability of a population.

Historical Data

The occurrence of populations in isolated habitat, especially on oceanic islands, gives us an idea of how large patches of habitat need to be for the long-term persistence of certain species. For example, in the Caribbean reptiles of certain species rarely occur on islands less than critical sizes, but they are consistently present on larger islands. This sort of island data can help us set MVHAs for particular taxa. As is known from island biogeography theory, islands are not isolated and their species complement is a consequence of local extinction and colonization processes. In this context, the presence of a species on an island may not reflect its long-term persistence,

only its recent arrival. However, where species have persisted on islands long enough to show variation from mainland populations, we can assume they have persisted for long enough to be termed viable. Although this general approach to PVA has been fruitful, the species that occur on these islands are usually not the same species for which we are trying to design reserve systems on continents. The question arises, how relevant is it to use data on MVHAs from one species for another species?

Extrapolation from Similar Species

Although we are unlikely to have data on the viability of, or MVHAs for, threatened species, it is possible that such information on similar, more common species can be used to assess viability. For example, we may know much about the fate of many small populations of a common species and use this information to determine the MVHA of a similar threatened species.

Expanding this line of thinking, some workers have begun to develop rules of thumb that relate extinction probability of MVHA to key life history attributes of a species, such as body size or home range size. We do know enough to say that predators can persist at much lower densities than herbivores of a certain size, and that larger animals and plants appear to be able to persist for longer periods in small populations than can smaller animals or plants. These fundamental patterns may enable us to draw broad conclusions about the viability of species and strategies for their protection with limited data and no predictive modeling. This crude approach may only be appropriate when data, time, and money are limited.

Testing Population Viability Analysis

Uncertainty about parameter estimates and the structure of PVA models means that their predictions may be inaccurate. As with any model, PVA is an imperfect description of reality, and model testing with real field data helps to identify the limits of its accuracy. The primary prediction of many PVA models is the risk of extinction of an endangered species over several decades or centuries. In such circumstances, we do not have the luxury to test the models by monitoring numerous populations until they become extinct. A sufficient number of populations rarely exist, and endangerment demands immediate management decisions.

Instead, we can test PVA models by predicting population attributes prior to extinction. The kinds of predictions that can be tested include the annual population growth rate, the population size in a series of years, the local population sizes in patches, and the probability of local extinction of patches (Brook *et al.*, 2000; Lindenmayer *et al.*, 2003). It is not sufficient to test the models by comparing mean predictions with observations because this ignores variability, which often is a critical factor influencing the risk of population decline. Tests of PVA models should investigate the distribution of the predictions – not only the average predictions but also factors such as the variance and predicted extremes such as local extinction. Replicates are necessary for such tests and may be obtained from annual observations over several years or from observations from several different locations. These tests rely

on appropriate data obtained from the field, which may require a substantial commitment to field surveys. As noted previously, we may need to test PVA models on more common species and then, by analogy, assume that they will work for threatened species. This requires a certain leap of faith.

Correspondence between the predictions of the model and observed data does not imply that the model is correct. Tests of PVAs may not be sufficiently powerful to identify the errors, or multiple compensating errors may exist. Regardless of how many times a PVA model has been tested, new data or a new test will expose the model to a chance of being proved wrong. This is similar to the scientific process of hypothesis testing.

Discrepancies between the predictions of a PVA model and observed data should not lead to complete rejection of the model. Instead, efforts should be made to identify the source of errors, which may be rectified to provide improved predictions. Identification of model errors is a useful part of model development. Such an approach to model testing is consistent with the use of PVA models as decision support tools. Improved PVA models should contribute to improved management decisions.

Criticisms of Population Viability Analysis: What Makes a Good Population Viability Analysis?

There is a healthy skepticism about the value of PVA. Although almost all authors acknowledge that PVA is valuable and a cornerstone of the science of conservation biology, PVA, like any tool, has been abused.

The following are major criticisms of PVA: (1) We don't have enough data to deliver reliable predictions; (2) PVA software packages are models that no one understands; (3) Results are very sensitive to uncertain parameters; (4) The models do not include important ecological processes. Because of the "black box" nature of PVA, there is concern that PVAs should be more explicit and detailed in their reporting of how the model works and exactly how the parameters were chosen. This is just part of good science – that is, whatever we do should be repeatable and transparent. Despite the diversity of PVA models, there is consensus on what constitutes a good PVA. Attributes of a good PVA include: (1) A description of why the PVA is being done (a motivation); (2) A fundamental understanding of the species' ecology, including what constitutes suitable habitat and the ability of the species to disperse between patches of habitat; (3) Detailed demographic data and the way in which demographic rates change with time and habitat. Care needs to be taken in describing exactly what parameters in the model do and exactly how they were estimated from data; (4) An understanding of the response of the species to threats; (5) An assessment of the current state of the population, acknowledging inaccuracies in the estimate (6) A statement about how the PVA is likely to help managers make decisions; (7) A description of constraints on decision variables and management options; (8) An understanding of the environmental disturbances that directly threaten (or indirectly threaten through habitat alteration) a species; (9) A detailed description of the model and data so that the PVA process can be repeated and extended; (10) An honest assessment of uncertainties in the data, processes that have been

ignored, and possible flaws in model construction and parameter estimation; (11) A sensitivity analysis.

Acknowledgments

This work was conducted initially as part of the Biological Diversity Working Group supported by the National Center for Ecological Synthesis and Analysis, a center funded by NSF (Grant No. DEB-94-21535), the University of California at Santa Barbara, and the State of California. Work by all three authors was also supported by several Australian Research Council grants and a Commonwealth Environmental Research Facility grant. We thank our numerous colleagues who have worked on PVA with us, especially Mark Burgman, Sandy Andelman, Bob Lacy, Drew Tyre, and Ian Ball.

Glossary

Apex predator An organism that occupies a food web's highest trophic level.

Bottom-up forces Population-regulating processes based on the availability of food, nutrients, and energy.

Carnivore An organism that consumes other animals.

Competitionism The view that competition regulates populations.

Food web The interconnections among organisms based on diet.

Herbivores Organisms that feed on plants and photosynthesizers.

Keystone species A strong interactor that is relatively rare.

Lotka–Volterra model An early equation relating rate of population change to the interplay between competition and predation.

Mesopredator A small to mid-sized predator.

Nutritionalism The view that bottom-up forces regulate populations.

Phytoplankton Microscopic primary producers that live in water column habitats.

Piscivores Predators that consume fish in aquatic habitats.

Planktivores Predators that consume zooplankton in aquatic habitats.

Top-down forces Population-regulating processes that originate from consumer limitation.

Trophic cascades A chain reaction of top-down interactions across multiple trophic levels.

Introduction

The science of ecology has undergone a succession of paradigms on the nature and importance of species interactions, including those between predators and their prey. The earliest view (henceforth termed nutritionalism) was that bottom-up forces (i.e., primary production and the efficiency of energy and material transport upward across trophic levels) regulate populations. Ecosystem ecology was built around this view of nature, which implicitly holds that apex predators, as the end points of energy and material flux, are of minor consequence to ecosystem function. Beginning in the late 1950s and early 1960s, the focus on species interactions changed to competition. In contrast with nutritionalism, competitionism holds that lateral forces within trophic levels regulate population abundance. By this view, predators are no more or less important than any other species. Top-down forces have begun to capture the attention of ecology, thereby legitimizing predators as important ecological entities. Ecologists now recognize that vital species interactions follow all three pathways (Figure 1), often simultaneously and sometimes interactively. Thus, although our focus in this article is on top-down forces generated by apex predators, understanding the ways in which predators influence biodiversity requires a more eclectic view of food webs and species interactions than simply “bottom-up versus top-down.”

The authors begin with a discussion of who the predators are and how they affect populations, communities, and ecosystems. They then present a series of case studies demonstrating the wide range of systems in which predation is an important organizing process, including examples of the unifying concepts and explanations of how they were

discovered. This discussion is followed by a theoretical exploration of predation and biodiversity. Next, the authors discuss the levels of biological organization at which predation can influence biodiversity and develop a conceptual

Figure 1 A simple stylized food web showing potential interaction pathways. The circles represent species, the downward-pointing arrows represent top-down forces, the upward-pointing arrows represent bottom-up forces, and the double-headed arrows represent competitive interactions. Although real food webs are far more complex, this figure shows the three main ways by which species interact with one another in nature.

model for how apex predators might influence the location and strength of bottom-up and competitive forces in systems under top-down control. The authors conclude by considering the needs and opportunities for further research on predators and how predators are likely to figure into the future of conservation biology.

Background and Definitions

What are Predators?

Most broadly defined, all consumers that utilize living tissues to the harm of another organism are predators, thus including a wide swathe of life, except for photo- and chemosynthesizers (plants and many microbes), decomposers, and detritivores. Even some plants – carnivorous species such as pitcher plants and the Venus flytrap – make part of their living as predators. Under this definition, predators would be represented by such diverse functional groups as herbivores, parasites (including microbes and parasitoids), and the immense diversity of invertebrate and vertebrate consumers that hunt and kill their prey. It can be difficult to pigeonhole predators based on simple assessments of trophic status, consumer–prey size relationships, or just about any other scheme. For example, herbivores such as elephants exist at one end of the consumer–prey size spectrum and microbes at the other, but it is uncommon for consumers in either group to kill their prey outright. Plants may even benefit from being eaten and a single act of predation by most microbes is of virtually no consequence to their prey because of the prey's immensely greater relative body size (hosts are killed not by single microbes but by enormous swarms of them). Although herbivores, microbes, and parasites are predators in this broad sense, our focus is on predators more in the sense of ordinary English, as a near-synonym for carnivore (an animal that feeds on the flesh of another animal), and in particular those that kill their prey outright and immediately on attack. Even this restricted definition includes a vast array of species and pertains to many fascinating ecological stories.

Species Interactions

The influence of predators on biodiversity depends first and foremost on direct predator–prey interactions. There is a huge amount of literature on these direct interactions. Almost any predator can, in some circumstances, directly limit the numbers or activities of its prey, and such limitation is of great practical importance in a wide range of applied ecology, such as pest control, conservation, and wildlife management. But the consequence of predation for communities and ecosystems goes well beyond these direct interactions, because prey species themselves interact with other species. Predation thus initiates proliferating chains of indirect effects, and these indirect effects are almost limitless, potentially causing populations to increase or decline anywhere in the interaction web. Because species are mobile, indirect interactions can even spill over from one ecosystem to another, at times over great distances. As will be shown below in several case studies, such indirect effects may involve long interaction chains, with

broad impacts on biodiversity and ecosystem structure and function.

Indirect Effects of Predators

An awareness of the indirect effects of predators can be traced back at least to the writings of Charles Darwin, who described an interaction chain leading from cats to mice to bumble bees to clover. Similar early examples were provided by such well-known ecologists as Charles Elton and G. Evelyn Hutchinson. Hairston *et al.*'s (1960) now-classic paper (hereafter HSS) was perhaps the first effort to mold the indirect effects of predation into a conceptual model of trophic interactions and population regulation. HSS recognized four trophic groups – producers, decomposers, herbivores, and predators – and argued that although herbivores are commonly limited by predators, plants, decomposers, and predators are ordinarily limited by resources. The HSS model has weathered the test of time, along the way setting the stage for several conceptual advances, including the importance of top-down forces in population regulation and community organization, the ideas of keystone species and trophic cascades, and a generalized theory of food chain dynamics. Each of these ideas or theories is briefly explained in the following sections.

Top-Down Forces

Bottom-up forces are those passing from producers to consumers, whereas top-down forces are those passing from consumers to producers. A Special Features section in the journal *Ecology*, published in 1992, stimulated further interest in the relative importance of these processes, in part by pointing out that top-down and bottom-up forces need not be mutually exclusive, even though bottom-up forces are necessary for the function of all ecosystems. This realization freed ecologists to imagine diverse influences of predation in nature. A recent volume (Terborgh and Estes, 2010) has synthesized many of these pervasive and richly diverse impacts of predation on natural and human-dominated ecosystems.

Keystone Species

HSS was followed in the mid-1960s by Robert Paine's highly influential paper on food web complexity and species diversity. Paine argued that predators often selectively consume and thus limit competitively dominant species, hence enhancing species diversity by releasing their subordinates from competitive exclusion. This argument was based on three essential premises: (1) predators selectively consume the competitively dominant prey; (2) in so doing, populations of the competitively dominant species are reduced; and (3) in the absence of predation, the prey guild is limited by interspecific competition. Paine's work captured the interest of community ecologists because it linked the influence of predators to species diversity, and (perhaps most important at the time) it was supported by results from field experiments. His studies of predation by sea stars on mussel bed assemblages were conducted in the temperate rocky intertidal zone where competition for space can be extreme. This also led to two

important developments in ecology: The idea of keystone species and the intermediate disturbance model of species diversity.

The intermediate disturbance model, further refined and generalized by Joseph Connell, holds that species diversity is influenced by the intensity of disturbance (either physical or biological; **Figure 2**). The basic idea is that there is often a tradeoff between ability to withstand or recover from disturbance factors, and competitive ability. When the intensity of disturbance is very high, those species that are vulnerable to disturbance are eliminated. When the intensity of disturbance is low, competitive subordinates are excluded by dominants. These limiting conditions are relaxed at intermediate levels of disturbance, thereby elevating species diversity. The notion of keystone species, as envisioned by Paine, applied to cases in which predators were the agents of disturbance, and species were competing intensely for space. Mortality factors which clear out some competitive dominants can free up space for species which are good at rapidly colonizing open areas. Although the definition of keystone species has broadened, on the one hand, to include other kinds of interactions and grown more restrictive, on the other hand, to exclude the effects of common species, this idea is rooted historically with the indirect effects of predators. Paine's intertidal study emphasized the role of predators in regulating the diversity of their prey, but keystone species also can influence the biomass of entire trophic levels, as is seen in trophic cascades.

Trophic Cascades

A trophic cascade is the progression of indirect effects by predators across successively lower trophic levels. HSS's proposed relationship between predators, herbivores, and producers was a generalized trophic cascade. Stephen Carpenter and James Kitchell popularized this idea based on the striking influences of predatory fishes on the essential components of

Figure 2 The intermediate disturbance model of species diversity. This model is based on the assumption that competitive exclusion occurs in benign systems. Thus, when the intensity of disturbance (including predation) is low, strong competitive interactions by the dominant species reduce species diversity. When the intensity of disturbance is high, species diversity is again low because those species that cannot cope are eliminated. Maximum species diversity occurs at intermediate levels of disturbance—strong enough to prevent competitive exclusion but not so strong as to directly eliminate species.

lake food chains – from minnows (the predatory fishes' prey) to zooplankton (prey of the minnows) and finally, to phytoplankton (prey of the zooplankton). There is growing evidence that trophic cascades occur broadly across diverse ecosystems.

Generalized Food Web Theory

A generalized food web theory was developed by Stephen Fretwell to show how predation, trophic cascades, and food chain length combine to predict the strength of plant-herbivore interactions (**Figure 3**). To understand this theory, first imagine an ecosystem with producers but no consumers. Lacking consumers, the producers are limited by competition for resources. Adding herbivores creates a two-trophic level system in which the plant populations become limited by herbivory. Adding predators limits herbivore populations, thus releasing the producers from limitation by herbivory and returning them to limitation by resource competition. The progressive increase of trophic complexity cascades downward through the food chain such that plant-herbivore interactions switch from being weak to strong as the respective number of trophic levels alternates between odd and even. This story can become more complicated and the expectations are fuzzier if consumers cut across trophic levels in their diets (e.g., the fourth trophic level may also consume the second level), but its essential features do show up in many ecosystems.

Next, the authors summarize some of the case studies that provide empirical evidence for these theories and concepts. Their presentation is organized around the various major biomes in which the work was done.

Figure 3 A graphical synopsis of Stephen Fretwell's theory of food chain length in systems under top-down control. The circles represent species or groups of species within particular trophic levels: ●, resource limitation; ○, consumer limitation. The solid arrows represent strong interactions, and the dashed arrows represent weak interactions. As food chain length becomes progressively longer, the plant-herbivore interactions alternate between being weak in odd-numbered systems and strong in even-numbered systems.

Case Studies

Rocky Shores

Studies of rocky seashores furnish the earliest and some of the most compelling evidence for the effects of predation on communities and ecosystems. The first well-known experimental studies were done by Connell in Scotland. Connell's work focused mainly on competition between the two barnacles (*Cthamalus stellatus* and *Balanus balanoides*) and predation on these species by the whelk (*Thais lapillus*). This research showed that the upper shore limit of *Cthamalus* was set by physical factors (weather) and the lower limit by competition for space with *Balanus* and predation by *Thais*.

Shortly thereafter, Paine began his studies of predation by the sea star (*Pisaster ochraceus*) in mussel beds along the outer coast of Washington. Paine hypothesized that sea star predation limited the lower distribution of mussels in the mid-littoral zone. This was subsequently confirmed by downward expansion of the mussel bed when the stars were removed. California mussels (*Mytilus californianus*) are the competitive dominants in this system. Predation by sea stars prevents mussels from controlling primary space (the rock surface), the principal limiting resource in this system, thus permitting other species to coexist within mussel beds. In the absence of predation by sea stars, mussels dominate space, thereby excluding the competitive subordinates (made up of many species, including barnacles, etc.) and reducing species diversity to a musseline monoculture. Subsequent research has confirmed a similar role for *Pisaster* elsewhere in western North America and for other species of mussels and sea stars elsewhere in the world.

Other predators also influence rocky intertidal communities. Work by Philip Hickey and colleagues demonstrated a trophic cascade among African black oystercatchers (*Haematopus moquini*), herbivorous limpets, and intertidal algae. Further studies of oystercatchers and limpets have confirmed similar interactions in South America, Australia, and western North America. Research in central and southern California further demonstrated how humans perturb the trophic cascade by exploiting owl limpets (*Lottia gigantea*, a large, territorial species) and by causing oystercatchers to abandon their breeding territories. The former effect causes a competitively subordinate guild of small limpets to replace owl limpets as the principal herbivore. The latter effect, induced simply by large numbers of humans being present along rocky shores, transforms the intertidal community from a three- to two-trophic level system. Small limpets come to dominate such areas, in turn reducing the algal cover. These human-caused perturbations probably are responsible for much of the modern-day character of rocky shores in central and southern California.

A final example of predation on rocky shores concerns the loco (*Concholepas concholepas*), a large muricid gastropod that consumes intertidal mussels and is exploited by humans in central and southern Chile. Juan Carlos Castilla excluded humans from a small stretch of shoreline at the Las Cruces Marine Laboratory near Santiago in order to better understand their influence on this system, and as expected loco abundance increased. The more surprising result was a shift in the

intertidal landscape, from one dominated by extensive mussel beds to one largely devoid of mussels. This particular example is noteworthy because it demonstrates how humans can perturb predator-mediated interaction chains with landscape-level consequences, and that reserves can be used effectively both to demonstrate and to mitigate such effects.

Kelp Forests

Kelp forest communities provide numerous examples of the ecological role of predators. Perhaps the most well known of these is that of the sea otter, which was hunted to near extinction in the Pacific maritime fur trade. Following protection in the early 1900s, the process of recovery created a fragmented population distribution within what had been a continuously occupied range. Contrasts between areas with and without sea otters revealed striking differences in kelp forest communities. Areas with sea otters supported lush kelp forests, whereas those without otters were extensively overgrazed by sea urchins, the otter's principal prey. These patterns result from a trophic cascade, driven by sea otter predation on sea urchins, thus releasing kelp beds from sea urchin grazing.

In addition to affording early empirical support for HSS, the sea otter-kelp forest system provides evidence for a wide range of predator-driven effects beyond those expected from simple trophic cascades. Sea otters influence numerous species by enhancing kelp abundance, thereby adding three-dimensional habitat and fueling increased primary production. This process is especially noteworthy because it shows how bottom-up processes can be altered by the top-down forces of apex predators. Other known or suspected consequences of sea otter predation in kelp forests are summarized in [Figure 4](#).

The influence of sea otter predation has several interesting historical dimensions. Faunal remains in Aleut kitchen middens show that sea urchin size distributions during most of Aleut prehistory were similar to those of modern systems lacking sea otters, thus suggesting that aboriginal humans, by limiting sea otters, influenced coastal ecosystems long before modern humans arrived on the scene. Evolutionary influences of sea otter predation appear over even longer time scales. The control of herbivores by sea otter predation has decoupled a coevolutionary arms race between kelps and their herbivores, thus resulting in the development of poorly defended plants and unresistant herbivores in the North Pacific Ocean. This hypothesis has been tested through a comparison with Australasian kelp forests, which lacked a predator of comparable influence to the sea otter and which contain well-defended macroalgae and herbivores that are more resistant to those defenses. This coevolutionary scenario may explain why Northern Hemisphere kelp forests have been so devastated by sea urchin grazing following decimation of their predators. It also may explain why Steller sea cows radiated from the tropics into the North Pacific Ocean, but not elsewhere, and why the world's most diverse and largest abalones occur in the North Pacific. The sea cows were sustained by their consumption of kelp, and abalone more diffusely benefited from the rich resources provided by the kelp environment.

The sea otter-kelp forest system has changed remarkably as killer whales entered the coastal ecosystem and began preying

Figure 4 A conceptual representation of the direct and indirect effects of trophic cascades in the sea otter-kelp forest system. The cascade is shown on the left, with a strong limiting influence by sea otters on sea urchins (heavy arrow) and a resulting weak limiting influence of the sea urchins on kelp (lighter arrow). Some of the known or suspected indirect effects of this trophic cascade on other species and ecosystem processes are shown on the right, with the black arrows indicating top-down forcing and the gray arrows indicating bottom-up forcing.

intensively on sea otters after their normal prey populations (seals and sea lions) declined. Since the early 1990s, killer whale predation has driven otter numbers downward by approximately an order of magnitude across large areas of western Alaska. The loss of sea otters has caused sea urchin numbers to increase and kelps to decline (Figure 5). This example illustrates that predator-prey interactions, acting through trophic cascades, influence herbivore-plant interactions in a manner consistent with the predictions described earlier for odd- versus even-numbered food chains (Figure 4). It further indicates a role for predators in linking ecosystems over large areas. This ecological chain reaction may have been set off by post World War II industrial whaling, which deprived killer whales of an important food resource and may thereby have forced them to broaden their diet to include these smaller species of marine mammals.

Other species of predators initiate trophic cascades in kelp forest systems. Robert Steneck and colleagues have argued that Atlantic cod (*Gadus morhua*) in the Gulf of Maine play a similar role to that of sea otters in the North Pacific. Predation by sheephead (*Semicossyphus pulcher*, a benthic feeding fish) and spiny lobsters (*Panulirus interruptus*) in a similar manner can limit sea urchins and enhance the warm-temperate kelp forests of southern California. Kevin Lafferty has argued that the loss of predators has facilitated disease spread in sea urchins in southern California kelp forests. This involves two distinct effects. An increase in urchin density permits disease transmission to occur more readily. Moreover, ecological theory predicts that predators which eliminate individual urchins

carrying a disease, thereby reduce the time over which it can distribute infective propagules. If m is the mortality rate of prey, the average lifespan of prey is $1/m$. Predators increase m , therefore reduce prey lifespan, and incidentally make it harder for infectious diseases to be sustained in the prey population. In the Southern Hemisphere, predation by rock lobsters (*Jasus lalandii*) in South Africa limits predatory whelks, in turn releasing subtidal mussel beds from limitation by whelk predation. Amos Barkai and Christopher McQuaid have argued that the loss of lobsters from these systems can lead to a predator-prey role reversal in which the hyper-abundant whelks turn to feeding on lobsters, thus leading to an alternative community state that is difficult or even impossible for lobsters to reinvade. A final example from kelp forest systems comes from the work by Davenport and Anderson, who have shown that planktivorous fishes protect kelp forests in southern California from overgrazing by mesoherbivorous zooplankton.

These several examples from kelp forest systems have shown that predators can shape populations and communities on ecological timescales and life history characters on evolutionary timescales. Comparative studies of sea urchins in tropical and temperate reef systems also suggest that predators influence their prey's behavior in complex ways. In warm temperate/tropical systems, sea urchins commonly retreat to protective cracks and crevices within the reef during daylight hours in order to avoid being eaten by diurnally active benthic predatory fishes. Fishes quickly attack urchins that are experimentally removed from their refuges during the day and placed on exposed habitats. Similar patterns have been shown for a variety of warm temperate and tropical systems in which benthic predatory fishes occur. However, the nature of urchin behavior appears to differ between species whose evolutionary histories are rooted in tropical versus temperate environments. Tropical species tend to display diel sheltering as a fixed behavior, regardless of ecological context, whereas the sheltering behavior is plastic in temperate species depending on whether predatory fishes are present or absent. The explanation for this difference in plasticity may lie in the fact that tropical urchins have long been subject to predation by diurnally active fishes, whereas temperate urchins have come into contact with benthic predatory fishes more recently in their evolutionary history, and only then at the warm margins of their geographical ranges.

Lakes

Numerous reports from various lake systems throughout the world show that altered populations of apex predators result in altered food webs. There are two main reasons for the number of studies and high quality of this evidence. Lakes, as discrete and recurrent entities, are well suited for comparative and experimental studies. Furthermore, the producers and herbivores (especially phytoplankton and zooplankton) have very short generation times, thereby making population-level responses to perturbations rapid enough for scientists to observe and document.

The essential players in lake systems include four main groups of organisms: phytoplankton, herbivores, planktivores,

Figure 5 (a) Changes in sea otter abundance over time at several islands in the Aleutian archipelago and concurrent changes in (b) sea urchin biomass, (c) grazing intensity, and (d) kelp density measured from kelp forests at Adak Island, Alaska. Error bars in (b) and (c) indicate 1 SE. The proposed mechanisms of change are portrayed in the marginal cartoons: The one on the left shows how the kelp forest ecosystem was organized before the sea otter's decline and the one on the right shows how this ecosystem changed with the addition of killer whales as an apex predator. Thick arrows represent strong trophic interactions, and thin arrows represent weak interactions. Reproduced from Estes JA, Tinker MT, Williams TM, and Doak DF (1998) Killer whale predation on sea otters linking coastal with oceanic ecosystems. *Science* 282: 473–476, with permission from AAAS.

and piscivores. The relationship of the first three of these to piscivore abundance, explained by cascading trophic interactions, is shown in Figure 6. The evidence for these interactions comes from a variety of areas and approaches. Early insights were provided by contrasts among lakes in which piscivore populations varied serendipitously but for unknown reasons. There are many such examples from tropical and temperate lake systems in both the New and Old Worlds. Additional evidence that these patterns are caused by trophic cascades has come from the results of mesocosm experiments, by tracking changes associated with the fortuitous extinction

or reintroduction of piscivores into particular lakes through time, and by whole-lake experiments in which the piscivores were purposely added or removed. Although the details vary depending on such factors as food chain length and the nature of particular species, the overall picture of food web dynamics in lake ecosystems is remarkably consistent, and especially highlights the ubiquitous importance of apex predators and trophic cascades in these systems.

Perhaps the earliest evidence for the influence of predation in lake systems comes from John Brooks and Stanley Dodson's analysis of New England lakes. These researchers showed that

Figure 6 Piscivore biomass in relation to biomass (solid line) and production (dashed line) of vertebrate zooplanktivores, large herbivores, and phytoplankton in lake systems. Reproduced from Carpenter SR and Kitchell JF (eds.) (1993) *The Trophic Cascade in Lakes*. New York: Cambridge University Press, with permission from CUP.

in the absence of planktivorous fishes, zooplankton assemblages were dominated by species with large body size because of their increased foraging efficiency and competitive superiority over small species. In lakes with planktivorous fishes, the composition of the plankton shifted toward small body size due to the influence of size-selective predation. This example was followed by Thomas Zaret and Robert Paine's report on the cascading influences of introduced peacock bass (*Cichla ocellaris*) to Lake Gatun, Panama. Peacock bass, a cichlid native to the Amazon River, were first introduced to Lake Gatun in 1965 for sport fishing and consumption. These introduced predators are voracious piscivores and they caused a remarkable series of food web effects as the bass population grew and spread across the lake. The immediate influence was a rapid and extreme reduction of planktivorous minnows, thus causing zooplankton populations, including that of mosquito larvae, to increase. This example added two interesting dimensions to the understanding of lake systems. One is the strength of influence by an exotic predator on naïve prey, with broad-ranging indirect effects across the lake and surrounding terrestrial systems. In addition to the top-down effects described previously in this section, the reduced populations of planktivorous minnows negatively impacted other apex predators, including several species of aquatic birds and predatory fishes. Another dimension is the potential impact on human health, in this case resulting from an increased threat of malaria because of increased mosquito populations. Similar examples of broad-ranging influences by exotic predators are known for many other lake and river systems throughout the world.

Lakes also provide intriguing examples of interecosystem linkages. For example, food subsidies from land to water, or in the reverse direction, can maintain populations of apex predators, thus reinforcing and even strengthening the effects of trophic cascades. Food web dynamics within lake systems can influence the surrounding terrestrial ecosystems, as demonstrated by Tiffany Knight and colleagues in Florida ponds wherein predation by fish on dragonfly larvae indirectly affects the numbers of adult dragonflies near pond margins. Adult dragonflies are voracious predators on insects, including pollinators such as bees and butterflies. The abundance of pollinators influences reproductive success in terrestrial flowering plants, so plants near ponds without fish have lower seedset than plants near otherwise similar ponds with fish. This

example also shows that trophic cascades can have impacts on mutualisms, not just herbivory. Trophic cascades have even been shown to influence the net flux of carbon between lakes and the atmosphere.

Rivers and Streams

Experimental work in rivers and streams has demonstrated influences of predation on food web structure and the life history of prey populations. Both fishes and birds are important apex predators in river food webs, and like lakes, many river food webs are strongly influenced by trophic cascades. The experimental exclusion of these predators from a variety of tropical and temperate river systems by Mary Power and colleagues provided evidence for top-down forces and has revealed depth-related gradients in the outcomes of trophic cascades. These findings show that the influence of predators on food webs can be strongly influenced by prey refuges, which in turn can vary across habitat gradients. Another important contribution of the riverine studies is that they have been done in systems that deviate in food chain length, thus providing the first experimental evidence that the strength of plant-herbivore interactions varies predictably between odd- and even-numbered food chains. Work by Andrew Sih and colleagues in streams of the eastern US also shows how the risk of predation can influence the interplay between feeding and reproductive behavior in several prey species. Barbara Peckarsky and colleagues have demonstrated similar phenomena in high mountain streams in the western US.

As described above for lake systems (see Case Studies: Lakes), there is growing evidence for diverse linkages between streams and adjacent terrestrial ecosystems. Both terrestrial and aquatic insects have been shown to affect food web dynamics in their respective adjacent aquatic or terrestrial habitats. Fausch and colleagues have experimentally documented that invasion of nonnative salmonids interrupts reciprocal flows of aquatic and riparian invertebrates, with effects that propagate within and across stream and terrestrial food webs. Nutrient subsidies from migratory salmon strongly influence the productivity of riverine and adjacent terrestrial ecosystems. And finally, terrestrial trophic cascades have major influences on both the hydrology and community composition of riverine systems in the western US, as exemplified by the work of Robert Beschta and colleagues.

The pioneering work of John Endler and David Reznick on Trinidadian guppies provides some of the strongest and most comprehensive evidence for the selective effects of predation. The risk of predation to guppies by various larger fish species varies within and among streams, and a variety of life history characters, color patterns, and features of guppy mating systems co-vary accordingly. By manipulating predator populations and translocating guppies among habitats, these researchers demonstrated rapid selective responses to altered risks of predation.

Tropical Reefs

Numerous recent studies document strong and far-reaching influences of predatory fishes in tropical reef systems. The exclusion of various predatory fish species has repeatedly been shown to cause population increases, changes in behavior, or changes in species composition of their prey guild, which in most cases are smaller fishes. Surveys of reefs around the world have shown that all but a few remote places now lack normal abundances of sharks and other large consumer species (such as groupers and wrasses) because of human exploitation. These reduced predator populations have led in turn to significant indirect effects that in some cases have led to phase shifts, including the collapse of corals. For example, the progressive exploitation of predatory and herbivorous fishes caused a large-scale phase shift from coral to algal-dominated systems around the island of Jamaica. In the tropical Pacific, outbreaks of the crown of thorns starfish (a coral predator), which in turn have devastated coral reefs, are now thought to be, at least in part, the result of reduced predation by benthic feeding fishes on the larval and juvenile stages of the sea stars.

Oceanic Systems

Although the oceans dominate our biosphere and provide critical ecosystem services in such diverse forms as food production and climate control, relatively little is known about the role of apex predators in the open sea. One reason is that the open sea and its associated seafloor habitat present serious logistical challenges to studies of any kind. Furthermore, many ocean ecologists still embrace the view that bottom-up processes are the main drivers of biological pattern in ocean ecosystems. Although bottom-up forcing in the sea is clearly important, this does not preclude top-down effects, which might be expected for several reasons. One is that strong predator-induced effects occur broadly in lakes and the general structures of ocean food webs (from phytoplankton to zooplankton to planktivores–piscivores) are similar to those of lakes. A second is that nowhere else on the planet are predators so abundant, as witnessed by the vast schools of marine mammals, seabirds, and predatory fishes, which still can be seen in places despite millennia of depredations by humans, and which historically were even more abundant. Despite these *a priori* reasons to expect cascades in the oceans, there are few examples of oceanic trophic cascades. One of these involves pink salmon (*Oncorhynchus gorbuscha*) populations in the North Pacific that fluctuate on a 2-year cycle. During years when pink salmon are abundant, zooplankton

are depressed and phytoplankton are abundant, whereas during years when pink salmon are rare, zooplankton are abundant and phytoplankton are relatively rare. Similar patterns have been documented following the reduction of cod in the North Atlantic Ocean and North Sea, and by the wholesale reduction of various predatory fishes in the Black Sea. In the Southern Ocean, the reduction of blue, fin, sei, and minke whales by industrial whaling may have released krill populations from limitation by predation, in turn elevating the carry capacities of other krill-feeders – pinnipeds, penguins, and perhaps additional groups of consumers. Increased growth rates and reduced age of first reproduction of seals and whales after the depletion of great whales from Antarctica have been interpreted as evidence for such effects. Changes in the isotopic composition in adélie penguin egg shell remains indicate that these birds were piscivores during most of the past 8000 years, shifting to a krill diet only after the onset of industrial whaling in the Southern Ocean early in the twentieth century.

Predation by gray whales (*Eschrichtius robustus*) and walrus (*Odobenus rosmarus*) has important effects on seafloor systems. Gray whales influence these systems by resuspending sediments and consuming amphipods. Furrows formed by the whales in the soft benthos are colonized by scavenging lysianassid amphipods, serve to accumulate detritus, and thus facilitate a local detritus-based food web. Walrus further impact these systems by consuming clams and other large infauna, in turn attracting predatory and detritivorous sea stars.

It is also becoming evident that sharks play important roles in many marine systems, especially at mid to lower latitudes. Ransom Myers and colleagues chronicled an irruption of small elasmobranchs and a resulting collapse of their bivalve prey following the reduction of great sharks from overfishing in the eastern US. Changes in the behavior of dugongs, sea turtles, and small cetaceans have been attributed to seasonal migrations of large sharks in Western Australia.

Behavioral patterns of various marine prey species also suggest strong predator–prey interactions. For example, krill and other large zooplankters typically undergo diel vertical migrations that take them beyond the foraging range of marine birds and mammals during daylight hours. Many species of forage fish and zooplankton form dense swarms, which probably reduce their likelihood of being consumed by predators that must search for and capture individual prey. Pagophillic (ice-loving) pinnipeds in the Arctic and Antarctica behave in fundamentally different ways in apparent response to whether the risk of predation is from above or below the ice. In the Arctic, where polar bears and humans are important predators, pinnipeds flee from the ice to water at signs of danger. In Antarctica, where the threat of predation is much greater in the water (from killer whales and leopard seals) than it is on the ice, the pinnipeds do not display such extreme flight behavior and often are nearly oblivious to potential disturbances when hauled out.

The authors suspect that more evidence of trophic cascades in oceans will emerge as oceanographers begin to incorporate it into their world view, particularly as the historical record is mined for evidence about ocean conditions prior to human impacts.

Boreal/Temperate Forests

Although terrestrial biotas of the New World once contained numerous large mammalian carnivores, the potential ecological significance of these predators was unknown until recently. There are many reasons for this prolonged state of ignorance. One is that the largest of these creatures – gray wolves and grizzly bears – were all but exterminated in the US and Mexico well before modern ecological research had taken form. Second, even if large carnivores have been able to persist in the face of direct persecution, they are extremely difficult animals to study due to their low densities, nocturnality, secretive habits, aggressive behavior, and wariness of humans. Third, just as ocean ecologists have downplayed the importance of predators in the open sea, many wildlife ecologists have tended to be skeptical about the importance of predation in population regulation, and this topic has been hotly debated in the wildlife literature. In a famous example, D. Irvin Rasmussen, Aldo Leopold, and then HSS attributed an irruption of mule deer on the Kaibab Plateau, subsequent overgrazing, and the eventual mass starvation of the deer herd to the extermination of gray wolves and other large predators, but Graeme Caughley later attempted to debunk this explanation. Fourth, the long generation times of key players (decades to centuries for trees; multiple years to decades for ungulates and carnivores) and the large areas required for the measurement or manipulation of their representative populations make rigorous study of the top-down effect of apex predators very challenging. Finally, political, social, ethical, and legal issues have dissuaded many scientists from studying large mammals.

Despite these difficulties, there is growing evidence for top-down effects by large predators in temperate and boreal forests. Brian McLaren and Rolf Peterson used historical information on wolf and moose abundance, together with growth ring measurements from balsam fir, as evidence for a trophic cascade at Isle Royale in Lake Superior (Figure 7). Wolf numbers have fluctuated substantially throughout the twentieth century, apparently in large measure because of demographic factors related to their small population size. Inverse changes in moose numbers followed wolf population fluctuations, thus suggesting regulation by wolf predation. Direct measures of changes in herbivory were unavailable. However, the distance between annual tree rings in balsam fir showed that sapling growth rates were lower when moose were abundant than when moose were rare.

William Ripple and colleagues have shown similar patterns elsewhere in North America, especially in the intermountain west. Tree ring analyses have demonstrated long-term recruitment failures of various tree species following the loss of wolves and other large predators to control programs in the early 1900s. Subsequent experiments in which deer and elk were excluded by fencing have established herbivory by large ungulates as a major cause of the tree recruitment failures. The reintroduction of wolves to Yellowstone National Park has contributed to the reversal of these patterns in some areas. Ripple and colleagues suggest that wolves have allowed for aspen recovery through a behaviorally mediated trophic cascade, with elk avoiding foraging in risky places, especially in riparian zones where they may be especially vulnerable to wolf predation. Recently, Kauffman and colleagues conducted a

landscape-level test of this hypothesis, and concluded that the cascading effect of wolves is likely mediated by wolf-induced reductions in elk populations and not by behavioral mechanisms of risk avoidance by elk. Wolf-induced trophic interactions have resulted in other effects on the ecosystem. For example, the loss of riparian vegetation has caused streams to channelize, in turn reducing water table levels. Reductions in the diversity of small vertebrate species, especially passerine birds, have accompanied these changes. The influences of wolves occur via other pathways as well. In the greater Yellowstone ecosystem, the reintroduction of wolves appears to have led to the reduction of coyotes and a resulting increase in fawn survival of pronghorn antelope.

Fragmented Coastal Scrub Habitats

Although experimental manipulation of terrestrial carnivores is exceedingly difficult, fragmented habitats can provide valuable, large-scale, ecological experiments to rigorously explore the top-down effects of mammalian predators. Large carnivores are particularly vulnerable to local extinction in fragmented landscapes due to their large ranges and resource requirements, low population densities, and direct persecution by humans. Larger carnivores can depress populations of smaller mammalian carnivores, or “mesopredators,” through direct predation, resource competition, and interference competition, including spatial and temporal avoidance. Consequently, the decline and disappearance of dominant carnivores in fragmented systems may lead to the ecological release of smaller predators that in turn threaten birds and other vertebrates. This process has been labeled “mesopredator release” and the phenomenon has been documented across a wide range of ecological communities, as chronicled in recent reviews by Laura Prugh, Justin Brashares, and colleagues.

In coastal southern California, intensive urbanization during the past century has destroyed most of the native coastal sage scrub and chaparral habitats, creating a “hot spot” of endangerment and extinction in the region and leaving undeveloped canyons dissecting coastal mesas to function as habitat islands immersed within a matrix of inhospitable urban habitat. Michael Soulé and colleagues proposed the mesopredator release hypothesis as a possible mechanism to explain the rapid disappearance of scrub-breeding birds from the habitat fragments. They predicted that the decline of the most common large predator (coyote) would result in the ecological release of native (striped skunk, raccoon, and gray fox) and exotic (domestic cat and opossum) mesopredators, and that increased predation by these particularly effective avian mesopredators would result in higher mortality and extinction rates of scrub-breeding birds.

To test this prediction, Crooks and Soulé exploited a serendipitous ecological experiment – spatial and temporal variation in the distribution and abundance of coyotes among these urban habitat fragments – to investigate direct and indirect effects of this top predator on community structure. In accordance with the mesopredator release hypothesis, lower visitation rates of coyotes in small, isolated remnants resulted in elevated numbers and activity of urban mesopredators.

Figure 7 The trophic system on Isle Royale, reconstructed for 1958–1994. (a) Wolf abundance calculated from aerial surveys; (b) moose abundance calculated from skeletal remains and aerial surveys; mean ring-width indices for balsam fir from the west (c) and east (d) ends of Isle Royale; and (e) actual evapotranspiration from April to October, a measure of water availability during the growing season. The shaded areas highlight intervals of forage suppression that the authors believe are closely tied to periods of elevated moose density, which in turn follow periods of low wolf density. Reproduced from McLaren BE and Peterson RO (1994) Wolves, moose, and tree rings on Isle Royale. *Science* 266: 1555–1558, with permission from AAAS.

Coyotes directly preyed on some mesopredator species, particularly domestic cats. Mesopredators temporally avoided coyotes as well. In fragments that coyotes visited episodically during the course of the study, mesopredator activity increased when coyotes were absent. As predicted, scrub bird diversity was lower in fragments with fewer coyotes and more mesopredators, even after accounting for the positive effect of fragment area and the negative effect of fragment age on bird persistence.

The top-down effect of coyotes on cats seems to have had the strongest impact on the decline and local extinction of

scrub-breeding birds in the urban fragments. Unlike wild predators, domestic cats are recreational hunters. Maintained well above carrying capacity by nutritional subsidies from their owners, they continue to kill even when prey populations are low. Using data on cat densities and predation rates, Crooks and Soulé estimated that cats surrounding a moderately sized fragment return approximately 840 rodents, 525 birds, and 595 lizards to residences per year. Such high levels of predation are likely unsustainable for many small vertebrate populations. For example, existing population sizes of some birds do not exceed 10 individuals in small to

moderately sized fragments, so even modest increases in predation pressure from mesopredators may quickly drive native prey species to extinction. Local extinctions of scrub-breeding birds are frequent and rapid; at least 75 local extinctions may have occurred in these fragments during the past century.

Trophic cascades generated by the decline of coyotes were embedded within a network of complex fragmentation effects that also exerted considerable bottom-up constraints on both predator and prey populations. Research in the San Diego canyons have demonstrated that a variety of taxa, including carnivores, rodents, birds, and invertebrates, require native habitat to persist, highlighting the importance of bottom-up limitations, including resources available for movement, foraging, cover, and shelter. In a study of reproductive success of scrub-breeding birds along a fragmentation gradient in San Diego, Douglas Bolger and colleagues concluded that the strength of top-down forces varied with characteristics of predator and prey and their species-specific responses along the urban gradient. Overall, this system again emphasizes how top-down and bottom-up forces work in concert to influence species diversity in terrestrial systems.

Midcontinent North American Prairies

The top-down effect of coyotes is evident in other systems as well. Historically, coyotes were generally confined to open plains and arid regions of western North America. The eradication of wolves from most of the continental US in the late 1800s and early 1900s likely facilitated the expansion of coyote populations. Currently, predator control efforts in the US are directed primarily at coyotes, and lethal and nonlethal measures have resulted in at least temporary coyote declines in some areas. In the Prairie Pothole Region of the North American midcontinent, coyote population reduction is considered one of the principal causes of increases in red fox populations starting in the 1930s; other carnivore species have been shown to increase in areas of coyote control as well. Although coyotes will kill red foxes, spatial and temporal avoidance, behavioral exclusion, and territorial shifting are likely the primary mechanisms by which coyotes reduce fox populations.

Red foxes are the most important predators on nesting ducks and their eggs and offspring in the prairie region. The ecological release of red foxes following coyote control has therefore resulted in increased predation on ground-nesting dabbling ducks, most notably mallards. Predation accounts for more than 70% of nest failures in these duck species, and in some areas intense predation on eggs, ducklings, and hens has been sufficiently intense to depress recruitment below replacement levels. Predation has resulted not only in population declines of duck species in the Prairie Pothole Region but also in altered population composition and skewed sex ratios. Similar processes are now thought to influence populations of certain upland game birds, including sage grouse.

Interestingly, since the mid-1970s, coyote populations have begun to rebound in parts of the Prairie Pothole Region due to restrictions in control and fur harvest methods and to reduced commercial value of fur. In these areas, expanding coyote populations have contributed to reduced red fox activity and

higher duck nest success; overall nest success in sites where coyotes are the principal canid is nearly twice as high as that in areas where red foxes dominate. Overall, the excellent series of studies by Alan Sargeant and colleagues in the Prairie Pothole Region highlight the changes in the canid predator assemblage in North America during the past century and emphasize the top-down community-level effects generated by these dynamic canid–canid interactions.

Tropical Forests

Some of the most dramatic evidence for top-down control by apex predators comes from research by John Terborgh and colleagues in New World tropical forests. Terborgh's vision of top-down control in this system stems from a contrast between Barro Colorado Island in the Panama Canal, and Cocha Cashu Biological Station in Peru's Manu National Park. Although the two sites are similar in climate and native biota, Barro Colorado Island, because of its small size and isolation from other forest habitat, lost its apex predators (jaguars, pumas, and harpy eagles) shortly after construction of the Panama Canal. Barro Colorado Island currently supports notably higher densities of herbivorous mammals, such as agoutis, coatimundis, sloths, and howler monkeys, than does Cocha Cashu – differences attributed to the loss of predators from Barro Colorado Island. These ideas were put to a more rigorous test by using recently formed habitat fragments – the islands of Lago Guri in Venezuela – as a large-scale ecological experiment. The Caroni Valley of east-central Venezuela, once a vast, unbroken forest, was substantially altered by the 1986 creation of a hydroelectric impoundment. Within this 120-km-long by 70-km-wide reservoir, Lago Guri, the emergent hilltops became islands – isolated fragments of tropical forest that varied in size and distance from the shoreline border of unbroken forest. Although the larger islands retain nearly complete vertebrate faunas, the smaller islands lost up to 90% of the native vertebrate species, including all of the large vertebrate predators. Resulting changes in the forest system have been swift and sensational. Populations of herbivore species such as leaf-cutter ants, howler monkeys, iguanas, and rodents (all seed predators or herbivores) have increased from one to three orders of magnitude. Indirect impacts on producers have been equally dramatic. Fewer than five of approximately 6070 native tree species are continuing to successfully reproduce, thus suggesting that highly impoverished floras will result from the loss of predators. Trophic shunts – the redirection of energy and material flux through the interaction web – have influenced populations of arboreal insects and insectivorous birds.

Justin Brashares and colleagues are discovering equally dramatic and wide-ranging effects of predators in Gabon. Long-term monitoring records by game rangers in several parks establish a gradual erosion of large predators, in this case lions, leopards, spotted hyenas, and wild dogs. Olive baboon populations have, in response, grown in abundance and expanded their diet (from one that was largely herbivorous and frugivorous to one that is now omnivorous and includes many smaller vertebrates). These changes appear to be causing not only a reduction in the abundance and diversity of

smaller birds and mammals, but also significant effects on the welfare of local humans. The increasing contact between baboons and people is facilitating the spread of disease. The baboons are also creating conflicts over agricultural resources, in turn causing villagers to hold their children out of schools in an effort to help defend their crops.

These examples illustrate two important points. First, predators often exert crucial roles in maintaining local species diversity. Terborgh's data indicate that the majority of tree species will eventually be lost from these islands systems, largely because of the loss of predators; Brashares' findings show similar losses in diversity of small vertebrates. These examples, together with the Crooks–Soulé study of fragmented coastal scrub habitats, also serves to remind us of the power of ecological experiments and the importance of scale (space and time) in designing studies on the role of apex predators in nature. It is highly unlikely that any amount of study of unperturbed terrestrial systems could have demonstrated the magnitude and breadth of effect by relatively rare apex predators. However, anthropogenically disturbed systems, such as fragmented landscapes, offer unique opportunities to understand the complex trophic interactions generated by large carnivores.

Exotic Predators on Islands

Perhaps nowhere is the top-down effect of predation on biodiversity so apparent as with the introduction of nonnative predators onto islands. Islands typically support few large predators and grazers, and apex predators such as mammalian carnivores are often absent. Consequently, insular endemic species regularly evolve in the absence of predation and thus lack adequate antipredator defenses. For example, many insular animals exhibit tame or fearless behavior that increases their vulnerability to introduced predators, and some island birds are flightless ground nesters. Similarly, many island plants do not produce the same noxious chemicals or physical defenses found in their closest mainland relatives – features that discourage herbivory.

Consequently, the introduction of nonnative predators can be catastrophic for sensitive island communities, to the point of driving insular prey species to extinction. The examples are numerous. Worldwide, of all the species that have gone extinct since 1600, 90% of the 30 species of reptiles and amphibians, 81% of the 65 mammal species, and 93% of the 176 species and subspecies of birds have been insular forms. Predation by introduced animals has been a primary cause for approximately 40% of the extinctions of birds on islands, and alien predators are endangering approximately 40% of currently threatened insular bird species. Introduced rats and domestic cats are notorious killers. Introduced rats have successfully invaded at least 80% of the world's 123 major island groups and are known to prey on a variety of insular vertebrates, including amphibians, reptiles, mammals, and birds. Indeed, predation by Pacific rats (*Rattus exulans*), black rats (*Rattus rattus*), and Norwegian rats (*Rattus norvegicus*) has been documented on at least 15, 39, and 53 insular bird species, respectively, and introduced rats are thought to be responsible for 54% of insular bird extinctions caused by predators. For

example, the introduction of black rats on Big South Cape Island, New Zealand, in 1964 resulted in the rapid extinction of five species of land bird, one species of bat, and an unknown number of invertebrates, including a species of large flightless weevil. On the Galapagos Islands, introduced black rats have reduced populations of the giant tortoise and the dark-rumped petrel by preying on eggs.

Mongoose and domestic cats have also been introduced to islands, at times deliberately to control nonnative rodents. Unfortunately, they instead often eradicate native prey species. On Hawaii, introduced mongoose had little impact on rodents but decimated flightless rail populations. Domestic cats have been accidentally or deliberately introduced to at least 65 island groups and are thought to be responsible for 26% of insular bird extinctions caused by predators. Incredibly, 375 cats on Macquarie Island near Australia killed an estimated 56,000 rabbits and 58,000 ground-nesting sea-birds each year. On sub-Antarctic Marion Island, 5 cats were introduced as pets in 1949 and by 1975 approximately 2000 cats were killing 450,000 burrowing petrels annually and were suspected of driving another petrel species to local extinction. In the mid-1900s, approximately five cats were introduced to Kerguelen Island in the sub-Antarctic and their descendants have killed more than 3 million petrels per year and are responsible for the extinction of several bird populations. In the most infamous and perhaps most extreme example known, the lighthouse-keeper's pet cat on Stephen Island, a tiny island off New Zealand, arrived in 1894 and within a single year it is thought that this one cat exterminated the flightless Stephen Island wren.

The effects of introduced predators extend far beyond their prey species and can include modification of ecosystem-level processes. For example, the New Zealand flatworm (*Artioposthia triangulata*) was accidentally introduced to the British Isles in the early 1960s and, with no natural predators, has spread rapidly. The flatworm is a voracious predator of native earthworm species. Earthworms, through their burrow excavation and casting activity, provide an invaluable ecosystem service by shaping the structure and hydrological patterns of soils. Flatworm infestations and the consequent depletion of earthworms alter both soil structure and hydrology. The ramifications are far-reaching and directly impact human welfare. By depleting native earthworms, the introduced New Zealand flatworm increases the risk of surface runoff and therefore the potential of soil erosion, agrochemical pollution, and flooding.

There are a growing number of examples of indirect effects of exotic predators on islands. Introduced arctic foxes (*Alopex lagopus*) in the Aleutian archipelago have decimated ground-nesting seabirds, in turn reducing the transport of nutrients from sea to land and causing the terrestrial plant community to shift from a grassland to maritime tundra. Introduced cats have similar effects on sub-Antarctic islands. In the northern Channel Islands of southern California, predation by golden eagles has caused a decline of the endemic and endangered island fox. Golden eagles, a terrestrial predator, colonized these islands from the mainland following the loss of the native bald eagles to DDT toxicity and the establishment of feral pigs on the island as a food resource.

Threatened prey species often recover, sometimes rapidly, when alien predators are controlled or eradicated on islands.

However, the removal of alien predators can also yield unexpected results. For instance, a recent eradication of introduced black rats on Bird Island in the Seychelles has resulted in a population explosion of exotic crazy ants (*Anoplolepis longipes*). Ironically, these ants are now threatening those bird colonies that the rat eradication was intended to protect. Furthermore, simulation models predict that on islands colonized by both cats and rats, elimination of cats may release rat populations, and that increased numbers of rats may actually increase predation pressures on island birds. In essence, this cascade represents another example of the mesopredator release phenomenon, with cats on islands as top predators and rats as the mesopredators. On a variation of the theme, controlling cats on islands that also support exotic rabbits may result in more rabbits, excessive grazing by these prolific herbivores, and severe impacts to insular vegetation and associated animal species; this example, therefore, directly follows the predictions from the models of HSS and Fretwell. Clearly, alien predators on islands represent a complex, unpredictable, and occasionally dramatic example of the relationship between predators and biodiversity.

Summary and Synthesis of Case Studies

It is abundantly clear from the preceding examples that the manifestations of predation in nature are dramatic and diverse, occurring at organizational levels ranging from the behavior of individuals to the dynamics of ecosystems, and on timescales ranging from ecological to evolutionary. Numerous studies show or suggest that predators influence the abundance, distribution, and population structure of their prey. Indirect effects of predation are less appreciated by scientists and the public, despite the fact that they occur broadly in nature, are important to ecosystem function, and often result in processes that benefit human welfare. Trophic cascades are the most common of known indirect effects. These may be nearly as ubiquitous in nature as the transfer of material and energy upward through food webs. In any case, ecologists should be more surprised by the absence of such top-down effects than by discoveries of new ones.

Despite extensive evidence for trophic cascades from many of the planet's major ecosystems, we know little else about their influences on overall food webs. The lake studies provide an important exception because here a relationship between the top-down effects of predation and the bottom-up effects of production has been shown. These findings indicate that predators may fuel production in odd-numbered food chains, and that maximum production across all trophic levels should be realized at intermediate intensities of predation. A corollary to this hypothesis is that the length of food chains under top-down control is necessarily limited not by production and the efficiency of energy transfer, but by the population constrictions that occur at consumer-regulated trophic levels. Such constrictions may be common in nature because intermediate intensities of predation probably occur rarely, except in highly managed ecosystems.

The theory of trophic cascades also provides guidance on where in a food web one might expect to find strong competitive interactions. Competition should be most strongly

manifested within trophic levels in which populations are resource rather than consumer limited. These occur at the odd trophic levels in odd-numbered systems and even trophic levels in even-numbered systems. Although this prediction requires further analysis, it provides hope for an integrated theory of what previously has been viewed and treated as the largely unrelated processes of top-down, lateral, and bottom-up species interactions. Moreover, apex predators can be paramount factors that govern the maintenance of species diversity in many systems, as modulators of competitive interaction as well as via direct impacts on prey.

Local extinctions and invasions of predators are increasingly common and can transform ecological communities, but unless these changes are observed or known from historical records, their significance in extant ecosystems may be difficult to understand. Often, extinct interactions are difficult to infer from historical records. As seen in some of the preceding examples, predation frequently leaves a mark on species-level characters, especially behavior, life history, and morphology. Geerat Vermeij's analysis of shell damage and morphological change (ostensibly from crushing predators) in Mesozoic marine gastropods provides a good example of one such record. The sudden increase in crushing predators was responsible for what Vermeij termed the "Mesozoic marine revolution." Using this perspective, Richard Palmer confirmed that shell structures indeed reduce the incidence of attack from crushing predators by experimentally removing spires from gastropod shells. Behavioral patterns also provide clues about the role of predators, as described in the case studies for sea urchins and pagophillic pinnipeds. Other examples could be cited, but those listed are sufficient to make the point that morphology and behavior, when thoughtfully and cautiously interpreted, frequently reflect evolutionary response to predation.

Although these examples provide insight into species-level responses to predation on historical timescales, they afford little insight into the food web effects of predators. For this purpose, one might profitably examine the characteristics of producers which have emerged over evolutionary history. Because of lags in evolutionary responses, many traits of plants today may reflect adaptations to trophic regimes that have vanished. Plants can deter herbivores by modifying their morphology, demography, and chemistry. The degree to which these defensive characters exist among plant species and populations sometimes indicates the intensity of herbivory on historical timescales, even if the herbivores are no longer present. Examples of this approach are provided by studies of differences in meristem location in steppe vegetation between the eastern and western slopes of the northern Rocky Mountains, variation in the resistance of birch trees to insect herbivores in boreal forests, the susceptibility to grazing damage in marine algae across coral reef habitats, and the evolution of reduced chemical and physical defenses in insular plants in the absence of herbivory. Many broad-leaved trees in New Zealand have a remarkable pattern in their development called "heterophylly." Up to a couple of meters in height, saplings have leaves that are thin, spiny, and have other traits that botanists believe would have made them poor forage for moas. Above the height of the tallest moa, the tree leaf forms radically change, becoming broad and soft. Moas went extinct

after the Maori colonized, but the plant traits today indicate the evolutionary importance of intense herbivory in these ecosystems. (As on many islands, predators were scarce in the fauna, so moas could reach very high abundance and penetrate most habitats.) Mismatches in extant communities between the intensity of herbivory and the degree of plant resistance sometimes can be taken as evidence for recent changes in top-down regulation, as suggested from the previously described contrast between Northern and Southern Hemisphere kelp forests. Similar approaches might be taken to discern the evolutionary importance of apex predators in other ecosystems.

What humans perceive as “dysfunctional ecosystems” are often consequences of the recently altered roles of predators (e.g., losses of native species or introductions of exotics). The authors are now beginning to see the ecological manifestations of predators and top-down forcing in places that a decade ago ecologists would not even think to have looked. These include effects on biodiversity, the success of invasive species, disease dynamics, fire ecology, carbon and nutrient sequestration, cross-ecosystem linkages, and even the composition and quality of water, soil, and the atmosphere.

Theoretical Studies of Predation and Biodiversity

The topic of predation and biodiversity involves interactions among multiple species at different trophic levels that interact in nonlinear, complex ways. A full understanding of this topic requires the analysis of mathematical and computer models, which permit one to keep track of multiple forces influencing the dynamics of interacting populations. This is particularly the case if one wishes to understand the factors governing the maintenance of species diversity. A noteworthy feature of the above case studies is that they often involve generalist predators which by feeding on a multiplicity of prey, link the dynamics of many species. So a particularly important area of inquiry is comparing specialist and generalist predators. A rich theoretical literature exists, exploring impacts of predation on the dynamics and structure of ecological communities. Here, the authors summarize highlights of this work, emphasizing conceptual insights rather than mathematical details.

A predator can influence whether or not a particular species is present in a community either by facilitating its persistence (i.e., predators can enrich species composition) or by preventing it from invading (i.e., predators can constrain species composition). If removing an apex predator greatly increases the abundance of a particular prey, and this prey is a predator on species at lower trophic levels, predator removal could indirectly lead to shifts in competitive interactions and thus persistence of species several trophic levels removed (as in a trophic cascade). Even if a predator does not dramatically affect composition, it may strongly influence relative abundances of resident community members. Finally, predators can influence the existence and magnitude of temporal fluctuations in abundance. Mathematical models help one understand all these effects.

To analyze mechanisms influencing species composition, we consider the growth of species when rare. If each species in a community increases when rare, diversity is maintained in

the face of perturbations. In theoretical studies, one writes equations describing the dynamics of each species and then analyzes this set of equations (e.g., with and without a top predator). To illustrate the basic approach, the authors discuss a simple model in detail and then briefly discuss results from other models. Theoretical studies suggest that there is no single relationship between predation and biodiversity but instead many relationships, depending on numerous contingent details of systems.

Predation as a Density-Independent Mortality Factor: Effects on Biodiversity

As discussed previously, predator removal can unleash competition among prey and induce a wave of additional extinctions. To understand this effect, the authors express the growth rate of each species as a function of three factors: $dN/dt =$ (inherent growth) – (effect of resident competitor) – (mortality from resident predator), where N is abundance. Predation may both facilitate coexistence (e.g., by reducing the abundance and impact of competitors) and hamper coexistence (e.g., by direct mortality).

The most basic effect of predation is increased prey mortality. The simplest form of predation is that described by a fixed, density-independent mortality term. Generalist predators can occasionally act in this manner. Assume that two species experience strong, direct competition, described by the classic Lotka–Volterra competition model with added mortality due to predation:

$$\frac{dN_1}{dt} = N_1 r_1 \left(1 - \frac{N_1}{K_1} - \frac{\alpha_{12} N_2}{K_1} \right) - m_1 N_1 \quad [1]$$

where N_1 is the density of species 1, N_2 is that of species 2, r_1 and K_1 are the intrinsic growth rate and carrying capacity of species 1, respectively, and the competition coefficient α_{12} is the effect of an individual of species 2 on species 1 (compared to the effect of 1 on itself). The second term expresses predation as density-independent mortality at a constant per capita rate m_1 . (A comparable equation for species 2, where we reverse the subscripts 1 and 2, completes the model.)

Using the criteria that each species should increase when rare, after some algebra the following condition for species coexistence emerges:

$$\frac{1}{\alpha_{21}} > \frac{K_1(1 - m_1/r_1)}{K_2(1 - m_2/r_2)} > \alpha_{12} \quad [2]$$

where the term $K_i(1 - m_i/r_i)$ is the effective carrying capacity of species i ($i=1,2$) in the face of predation. This inequality implies several interesting conclusions. If $\alpha_{12}\alpha_{21} > 1$, no pattern of imposed, density-independent mortality leads to coexistence. This in effect says that interspecific competition is always stronger than intraspecific competition, and no fixed pattern of mortality will reverse this and permit coexistence. Likewise, if competition coefficients are unity, one will not observe coexistence, regardless of the pattern of mortality. If the two competitors have the same intrinsic growth rate, and predation is uniform (or more generally, $r_1/m_1 = r_2/m_2$), mortality drops out, so there is no effect of predation on coexistence. So clearly there will be some circumstances where predators will not facilitate coexistence of competing prey.

However, if $\alpha_{12}\alpha_{21} < 1$, coexistence is possible in Lotka-Volterra competition. Predation can now facilitate such coexistence, if the two competitors differ in the ratio r/m . Consider a case of a competitive hierarchy, such that $\alpha_{12} = 0$ but $\alpha_{21} > 0$, and assume that species 2 is competitively excluded in the absence of predation. This happens if $K_2 < K_1\alpha_{21}$. With the predator present, coexistence is permitted if $K_2(1 - m_2/r_2) > K_1(1 - m_1/r_1)\alpha_{21}$.

Comparing this inequality to the previous one, after a bit of manipulation it can be seen that a necessary ingredient for predation to facilitate coexistence is that

$$r_1/m_1 < r_2/m_2$$

In other words, the dominant competitor must either experience higher mortality from predation or have a lower intrinsic growth rate, than does the subordinate. However, if predation is too low (low m 's for both species), there will still be competitive exclusion. Moreover, if predation is too intense, there will not be coexistence because one (or both) species will be directly eliminated by predation.

This model illustrates several general points applicable to a much broader range of models. First, predation does not always facilitate coexistence. Second, if a keystone predator effect is possible, the effect occurs only within a particular range of population parameter values, so will vary contingently with environmental conditions. Typically, predator-mediated coexistence requires an intermediate level of predation. Very intense, generalized predation will almost always reduce species richness. This is particularly likely in systems in which prey species have not had a shared evolutionary history with predators (e.g., the brown rat snake as a predator on birds on Guam), the physical structure of the environment makes it easy for predators to encounter prey (e.g., no refuges, as in open lakes), or the species in question have low intrinsic growth rates and so cannot readily replenish losses to predation. Third, predator-mediated coexistence requires a tradeoff: The species that is the superior competitor needs to be more vulnerable to predation. When this occurs, predator removal will endanger the persistence of inferior competitors (as in Paine's *Pisaster*). Another quite general point is that the appropriate measure of a species' vulnerability to predation combines mortality rates (m) and the ability to replenish losses (r). High, uniform rates of mortality tilt the balance of competitive interactions toward species with high intrinsic growth rates. Growth rates will usually depend on resource availability. Thus, bottom-up factors are involved in determining the outcome of a top-down process. Finally, along a gradient in predation pressure, provided there is a tradeoff between competitive ability and vulnerability to predation, the model predicts that species richness should be maximal at intermediate predation rates. We have seen this idea earlier, in the intermediate disturbance hypothesis of Connell (albeit without being dressed up in algebra).

This model structure assumes that predation influences competition entirely via changes in prey abundance. However, prey can also show behavioral shifts when faced with predators – for instance, spending more time in refuges and less on foraging. Such “higher order interactions” (often termed risk averse or trait mediated effects) can either make coexistence

more difficult or weaken competition, depending on the detailed nature of the behavioral changes.

The Lotka-Volterra model most literally applies to systems with strong, direct interference interactions, in which the only dynamical variables are each competing species density. In models of exploitative competition for a single limiting resource, predation that leads to density-independent mortality can influence which species wins, but it will not as readily lead to coexistence. Predation is more likely to promote (or occasionally to destroy) coexistence when mortality rates are dynamical variables responding to prey abundance, for instance because predator numbers or behavior shifts in accord with prey availability. The authors next explore several modifications of this model which illustrate the rich repertoire of dynamical behaviors made possible when predation varies dynamically in response to prey abundances.

Numerical and Functional Responses

The rate of mortality imposed by a predator reflects both predator numbers and the attack rate per predator. The total rate of mortality in the above model is $mN = fP$, where P is predator density and the parameter f is the number of prey (of the focal species) captured per individual predator. Because predators consume prey, the rates of the demographic parameters (birth, death, and movement) of predators will often vary as a function of the abundance of prey. Thus, the number of predators should depend on prey numbers. This is the numerical response. The rate at which an individual predator captures prey of a given species should also depend on the number of prey that are available, typically (although not always) increasing with prey abundance but saturating at high prey numbers. This is the functional response. It is useful to express the functional response as $f = aN$, where a is the attack rate per predator per prey – the risk of mortality an individual prey faces from an individual predator. Holling in 1957 introduced the distinction between predator functional and numerical responses as an essential step toward understanding the stability of direct predator-prey interactions, but these concepts also are significant in understanding the role of predation in maintaining prey species diversity. Different predators have distinct numerical and functional responses and therefore will have different impacts on species coexistence.

If predators strongly interfere with one another, this can weaken both functional and numerical responses to their prey. If we consider predators at intermediate trophic levels, higher order predators can also strongly dampen functional and numerical responses. For instance, active foraging by intermediate consumers may attract the attention of higher order predators. If so, adaptive responses by the intermediate consumers may keep in check their own attacks on prey, thus weakening both functional and numerical responses to increased prey abundance. Understanding the consequences of such flexible behaviors for food web dynamics is a very active area of current research. The case studies of strong top down effects sketched above can be viewed abstractly as emerging from the interlocking of functional and numerical responses by consumers across trophic levels.

Specialist Predators and Biodiversity

Specialist predators (whose diets are restricted to single prey species) typically reduce abundance of their favored species, freeing up resources for nontarget species. This can facilitate coexistence if dominant competitors attract more specialist predators or parasites than do subordinates. This diversifying effect of specialized predation can be mimicked in (1) by letting the attack rate on each species be a function of the abundance of a specialist predator, $m_i N_i = a_{ij} P_j N_i$, where P_j is the abundance of predator species j , which is specialized in its foraging just to prey species i . To complete the model, we need an equation for the dynamics of each predator: $dP_j/dt = P_j[g_j(N_i, P_j)]$, where g is a function which increases with N_i (e.g., because predators convert prey consumption into births) but may decrease with P_j (e.g., because predators interfere with each other). For any biologically reasonable system, at low numbers of their required prey, specialist predators must decrease (i.e., $g < 0$). Hence, the growth rate of prey species i when it is rare and other prey are resident, will involve only the intrinsic growth of prey i , discounted by competition with the resident species. Because the residents continue to be attacked by their own specialist predators, their numbers will be depressed below carrying capacity, reducing competition imposed on the rare focal species. Thus, specialized predators quite generally are expected to facilitate prey coexistence. Moreover, a specialist predator that is effective at limiting a prey species that otherwise would be a dominant species, therefore has a strong indirect effect on the rest of its community and ecosystem.

An interesting twist is that specialist predator-prey interactions are often unstable when the predator is very effective at limiting prey numbers because of time lags in the numerical response of predators to prey, including crashes by predators that follow declines in their prey. This has two consequences for species coexistence. First, as shown by Peter Abrams and others, with saturating functional or numerical responses, instability tends to depress average predator numbers and thereby increase average prey numbers. This increases competition, making coexistence of different prey species more difficult. Second, with unstable dynamics between a resident specialist predator and its prey, there will be times when that prey is rare and an inferior competitor can invade and temporarily persist, only later to be competitively excluded when the predator is rare and the dominant competitor has rebounded in numbers. Thus, unstable specialist predator-prey dynamics induces instability in prey community composition as well.

These effects are believed to be particularly important when considering impacts of insect herbivores on plant communities, and pathogen dynamics can lead to unstable dynamics as well. For instance, forest insects and pathogens can outbreak and devastate large swaths of tree populations, and thus drive pulses in detritus and major changes in vegetation structure, impacting most species in those communities. However, most predators in the case studies discussed in this article have generalized diets and seem less prone to boom-and-bust dynamics (though data are scant on this point).

Generalist Predators and Biodiversity**Switching and "Enemy-Free Space"**

The expectation that specialist predation helps competing species to coexist depends on the very general and reasonable assumption that specialist predators will have strong numerical responses to their prey. Generalist predators can have a wide range of effects on prey communities. A single, effective generalist can act like a whole suite of specialists in promoting prey coexistence if the predator ignores whichever prey species is temporarily the rarest, concentrating attacks on common prey – the mode of foraging behavior called switching. As shown by Roughgarden and Feldman, switching predators can readily prevent competitive exclusion. In our formulation for mortality due to predation, for example, on prey species 1, $m_1 N_1 = a_1 P_1 N_1$, we can represent switching with an attack rate expressed as $a_1(N_1, N_2, \dots)$, where a_1 declines toward zero as N_1 approaches zero but increases if the other N_i decrease. In effect, a prey species may persist because of a refuge in relative rarity, as defined by the predator's behavioral responses. Because the predator is also reducing the abundance of potential competitive dominants, this is a potent mechanism for predator-mediated coexistence. When such a predator is removed, numerous prey species may suddenly risk extinction if they compete, because such competition will become more intense as prey numbers rise after release from strong predation.

This idea is intuitively appealing, but there are surprisingly few unequivocal demonstrations of it in natural systems. Moreover, those that do, seem to involve prey species found in different habitats. A behavioral rule such that predators leave patches with few prey, and aggregate in patches with numerous prey, leads to switching and will tend to foster prey coexistence. If prey species are spatially segregated, they are not likely to be strongly competing in any case. Other potential cases of switching seem to involve prey species with very different strategies for blending into the background, different activity times, or different behavioral tactics for escaping predation. John Lawton and Michael Jefferies suggested that such species differences promoting coexistence be viewed as partitioning of enemy-free space, an aspect of niche differentiation.

In any case, several examples of species exclusion caused by predation discussed elsewhere in this article show that predators often do not tend to ignore rare prey species but rather continue attacking rare prey, even to the point of extinction.

Saturating Functional Responses

All predators have a maximal capacity for attacking prey that is set by limited time or gut capacity. Time or effort expended in attacking one prey will be unavailable for attacking other prey. If predator numbers are fixed, an increase in abundance of one prey species may reduce attacks on another. As with switching, we can represent this as $a_i = a_i(N_1, N_2, \dots)$, but now attack rates decline with the abundance of each species. This inverse density dependence has two consequences. First, considering the effect of a prey species on itself, its mortality diminishes with increasing abundance. This inverse density dependence can lead to alternative stable states for a given

prey species – one at low and another at high densities. The low-density equilibrium may even be at zero density. More generally, at low densities a predator may have an accelerating functional response, but saturate at higher prey numbers (Holling's Type III functional response). It is believed that this effect is responsible in part for prey outbreaks, where prey may be regulated at low numbers by predators, but when perturbed they can sometimes escape to explode to much higher numbers. Second, in a community context, with a saturating response, an increase in any prey species can have a short-term effect of reducing attacks on other prey species; this in effect makes alternative prey indirect mutualists, at least over short time scales. Such mutualism is most likely when considering predators that are constrained and sluggish in their numerical responses to increasing numbers of prey (e.g., due to long generation lengths relative to those of their prey, and low in mobility, and at intermediate trophic levels).

Unlike switching, saturating functional responses are universal. The existence of indirect mutualisms arising because predator functional responses can be swamped may explain many natural phenomena, such as herding, mixed-species flocks of birds and schools of fish, and synchronized mass emergences and migrations. One consequence of importance to biodiversity is that if some prey species are reduced in abundance, there is an immediate increase in predation on other alternative prey, which thus risks extinction.

Numerical Responses and Apparent Competition

The potential for indirect mutualism among these taxa via the functional response is often offset by a kind of indirect competition via the numerical response. The case studies above show that apex predators can have dramatic effects on prey, leading to chain effects of indirect interactions across entire ecosystems. In most of these examples, the predators are generalists and have different magnitudes of impacts on different prey species. The sea otter for instance eats bivalves, snails, other invertebrates, and fish, in addition to urchins, and its ability to reduce urchins to very low levels depends on the availability of a range of alternative prey types which can sustain healthy otter populations. This implies the existence of another kind of indirect interaction through species on a given trophic level, but mediated through consumers, rather than resources. Just as consumer species can reduce each other's abundance by depleting a shared limiting resource, alternative prey species can indirectly depress each other's abundance by increasing the abundance of a shared predator. This indirect interaction is known as apparent competition. It is particularly likely if predator population growth rates increase strongly with the abundance of each prey type in the predator's diet and predator numbers are not strongly limited by other factors (e.g., territoriality or higher order predators). It is also somewhat more likely for predators with short generation lengths, not greatly exceeding those of their prey (e.g., parasitoids attacking herbivorous insects), or for predators which are highly mobile and can quickly aggregate into habitats with unusually high prey densities.

When any given prey species is rare, an increase in predator abundance will usually lead to an increase in its mortality. Predator abundance is expected to increase with the productivity and availability of alternative prey. The rate of

predation on a focal prey is thus determined by the indirect, cumulative impact of alternative prey, sustaining the predator population at densities higher than permitted by the focal prey, considered alone. Particularly when prey species are not strongly competing, the negative indirect interaction of apparent competition can limit prey species diversity.

When a prey species is rare, its rate of population growth can be represented as $r - aP$. As noted previously, often the presence of alternative prey reduces the attack rate on a rare species. However, these same prey determine the magnitude of P . The net effect of prey on each other can only be determined by analyzing specific models. However, some general points are worth making. A given prey species is excluded by predation if $0 < r < aP$. Prey species with low r are particularly vulnerable to exclusion by shared predation, as are species which have high attack rates. Another way of stating the exclusion criterion is that the maximal predator density which this prey can tolerate is r/a . All else being equal, prey with low values for r/a are vulnerable to exclusion. A comparable observation was made below for the above model for predation as a density-independent mortality factor, but the difference in this case is that now the level of predation is itself a dependent variable in the system, and in particular depends on the availability and productivity of the entire suite of prey that sustain the predator. Note that a prey species with a high value for r/a can support a high abundance of a generalist predator, which can then with impunity overexploit alternative prey with lower r/a . The upshot of these observations is that there is a tendency toward the exclusion of prey species in the diet of polyphagous predators. The maintenance of high diversity requires mechanisms that offset this effect. Such mechanisms might include predator switching, constraints on the predator numerical response, or prey adaptations that reduce predation at low density (e.g., spatial refuges, with different prey species having different refuges).

Often, apparent competition will be strongly asymmetrical. A productive prey, which also can only be successfully attacked by predators when it is young, ill, or aged, may not be strongly limited by predation. However, this species can sustain a high population of the predator, which can then severely depress species more vulnerable through their life history. If different prey species occupy different habitats, and predators have limited mobility, this too can prevent exclusion via shared predation. However, mobile predators can be sustained by productive prey in one habitat and with impunity can overexploit prey in low-productivity habitats. A serious effect of habitat fragmentation is that it exposes species in habitat remnants to predation from generalist predators sustained by alternative prey in the surrounding landscape. Most examples of dramatic prey limitation by predation seem to depend on the availability of alternative prey, which permit predator numbers to remain high. The brown rat snake on Guam can persist on a diet of rats and lizards, which permits it to eat out of existence native bird species. Subsidies for predators (e.g., flows of prey from one habitat to another; a lighthouse keeper feeding her cat) in particular can permit a predator to exploit vulnerable prey to the point of local extinction.

Previously, the authors discussed the cascading effects of top predator removal. Such removals shift the factors regulating intermediate mesopredators or herbivores, which will

increase and become more regulated by food availability than they were in the past. This can unleash strong apparent competition effects at lower trophic levels, often on prey species which have evolved with relatively low levels of predation in their environment. Prey species harmed by polyphagous predators via “mesopredator release” are victims of apparent competition.

Generalist Predators and Community Stability

Generalist predators can have many different effects on the overall stability of communities. Here, the authors discuss a few interesting effects.

Richard Vance examined a Lotka–Volterra model akin to (1) but with a predator showing numerical responses to each prey species. Even if the pairwise interactions were all stable, the entire ensemble could show large-amplitude cycles, or even chaotic dynamics.

If generalist predators are mobile and seek out patches with high prey abundance, this can lead to switching. If these responses are rapid, then generalist predators help stabilize prey dynamics. However, there can be time lags in these responses, which in turn can be destabilizing. Recent theoretical explorations suggest that switching behavior in patchy environments leads to systems which persist but which have bounded oscillations. Moreover, in changing landscapes, mobile generalist predators can concentrate in habitat remnants, leading to transient spikes of high predation and extinction risk for prey species residing in these remnants.

Generalist predators usually have a mixture of a few strong interactions and many weak interactions with the species of prey in their diet. Theoretical studies have recently demonstrated that weak interactions can help reduce inherent instabilities in strong predator–prey interactions. However, the effect depends on detailed assumptions made about predator–prey feedbacks; for instance, if prey flow into a given habitat and contribute to the diet of a resident predator, this predation does not feed back to influence prey numbers in the source habitat. If the predator instead is highly mobile, its ability to feed in multiple habitats may permit severe over-exploitation of prey in some habitats. Despite such cautionary tales, many ecologists are convinced that flexible foraging by generalist predators is broadly an important factor stabilizing complex food web interactions.

Given saturating functional responses, apparent competition can be reduced in unstable systems, relative to stable systems, because the nonlinearity in the functional response means that predators are harmed more by times of low prey abundance, than benefited by times of high prey abundance. This reduces the number of predators which can be sustained, thereby weakening apparent competition effects. The dominant effect may then be competitive exclusion (if the prey are strong competitors) or indirect mutualism (with noncompeting prey and saturating functional responses).

If a prey species is dominant in apparent competition, this may permit it to persist with a superior competitor, in effect being maintained by generalist predation. As noted above, selective predation, particularly by specialist predators, can help offset competitive exclusion. Peter Chesson and Jennifer Kuang

have recently developed, in some detail, the insight that predation and competition are likely of comparable importance in explaining coexistence, and that a multitrophic perspective needs to replace the past focus on competitive interactions and niche partitioning to have a full understanding of the factors that maintain the rich diversity of natural communities.

The theoretical studies summarized here suggest that there is no universal effect on predation on biodiversity but rather many effects. More important, they help emphasize potential surprising effects of predator removal and highlight the range of information that a conservationist needs to gauge the likely impacts of management alternatives. Most theoretical studies of how predation impacts species diversity have been limited to interactions across two-trophic levels. More complex theoretical studies of trophic interactions are needed to investigate such phenomena as trophic cascades and their indirect effects on other species and ecosystem processes in more complex, multilevel food webs.

Generality

There is much evidence for the influences of predators on species, populations, communities, and ecosystems. However, how predictable and widely occurring are these effects? To what degree do predators regulate the structure and function of the planet’s ecosystems relative to other biological interactions and physical forces?

These important questions can be asked at two levels – within and between ecosystems. Within systems, the question of generality usually concerns the geographical extent of an effect that has been demonstrated at one or several sites. Michael Foster raised this question for the influences of sea stars in mussel beds and sea otters in kelp forests, claiming that the interactions were less common than generally believed. Not surprisingly, sea star predation is important at many sites but not everywhere. For sea otters and kelp forests, Estes and Duggins approached the question by evaluating how consistently predictions of the otter–kelp forest trophic cascade played out at many sites with and without sea otters. In this case, the predictions held up (i.e., otter-dominated sites supported kelp forests and otter-free sites were deforested by sea urchin grazing) nearly everywhere they examined, from southeast Alaska to the western Aleutian archipelago (Figure 8), and similar results have been obtained from British Columbia.

Across ecosystems, the question of generality for top-down influences of apex predators becomes one of both relative importance and variation in process. This question is exemplified by the indirect effects of wolves on aspen recruitment in the greater Yellowstone ecosystem. Herbivory by elk has been established as a key limiting factor to aspen recruitment in many areas across the intermountain west. The reintroduction of wolves to Yellowstone has resulted in a striking flush of tree recruitment in the Lamar Valley region, thus suggesting that the repatriation of wolves would reverse the long-standing decline of aspen over much larger areas. However, Matthew Kauffman and colleagues have shown that aspen recruitment has not increased over most of Yellowstone’s northern range, thus calling into question the generality of the wolf–elk–aspen trophic cascade. Whether the cascade is truly of only limited

Figure 8 Epibenthic kelp density plotted against estimated sea urchin biomass from locations with and without sea otters in the Aleutian Islands and southeast Alaska. Points represent averages of 20 randomly selected plots from each location. These data show that kelp forest phase states vary predictably depending on the presence or absence of sea otters. Reproduced from Estes JA and Duggins DO (1995) Sea otters and kelp forests in Alaska: Generality and variation in a community ecology paradigm. *Ecological Monograph* 65: 75–100, with permission from ESA.

occurrence or there has simply been insufficient time since the wolf introduction for the system to respond broadly remains uncertain. We know that trophic cascades occur broadly in nature. Nonetheless, understanding the breadth of influences by predators remains one of ecology's most daunting challenges. The theoretical perspectives sketched above show that many effects in principle can happen, but being able to predict which occurs where is beyond what ecologists can presently do. But if we hope to devise strategies for the wise long-term management and preservation of natural systems, this challenge must be tackled.

The Future

Although predators have long concerned conservationists and resource managers, the future will – or should – bring

heightened attention to this group. As a general rule, apex predators are more vulnerable to local extinctions than are lower trophic-level species. The rapid demise of predators has occurred in part because they have been (and in many areas still are) treated as competitors of humans for fish, wildlife, and agricultural resources; thus, they have been persecuted rather than conserved. Habitat fragmentation has also hastened local extinction rates of large apex predators because their typically low densities and large home ranges render the smaller fragments incapable of maintaining viable populations. Large-bodied predators typically have long generation lengths and low reproductive rates, so populations cannot readily withstand mortality inflicted on them by, for example, hunting and toxins. These facts, together with the growing realization that predators are commonly essential for maintaining native ecosystems, are leading to a paradigm shift in conservation biology, especially in the area of reserve design. Earlier approaches to conservation planning focused on preserving representative habitats. Many ecologists now believe that this approach, although necessary, is not sufficient. Large reserves, or a series of smaller connected reserves, are necessary to maintain viable populations of key species of predators, and in particular apex predators (typically vertebrates), which in turn are essential for maintaining the functional integrity of ecosystems. This view has important implications to restoration ecology, which until recently has focused mainly on the reintroduction of native plants and the elimination of exotic species, with scant attention given to building viable entire food webs.

If the maintenance or restoration of native predators is important to conservation biology, so is the elimination of exotic predators. Exotic predators have devastated many natural biotas, both because of their ability to reduce or exterminate native prey species and because of the many indirect effects of these prey within the ecosystem's interaction web. As discussed previously, island biotas provide the most obvious and poignant examples of such effects. The removal of exotic species is usually expensive, time-consuming, and fraught with technical challenges. Nonetheless, exotic predators, because of their great mobility and low population density, are often easier to remove than other invasive species.

The conservation and management of predators require more and better information than is currently available. As noted by George Schaller, field studies have been conducted on less than 15% of the species of mammalian carnivores. And even of these, there are few predators for which enough information is available that one could write down credible expressions for functional and numerical responses of the sort that are essential for management and predictive models. Although this is indeed a feeble record, the authors suggest that there are even fewer successful efforts to understand the ecological importance of this group.

Are all or most of the predators important players in prey population regulation and ecosystem dynamics? The fact that so many species already have been depleted or eliminated hampers the pursuit of answers. The depleted status of so many predators raises the additional question of how their influences vary with population density. Most apex predator populations probably were once regulated by competition for food, which in turn must have strengthened predator-prey

Figure 9 Several possible functional relationships between predator-induced interaction strengths and predator population abundance relative to equilibrium density. In A (solid line), the relationship is linear. In B (dashed line), the main influences of predators occur at a wide range of population densities, whereas in C (dotted line) these influences occur only at high population densities.

interactions imposed on lower trophic levels. However, humans have changed this, so we must now wonder how the strength of these interactions varies with the degree to which predators have been pressed below historical average levels. The several possible functional relationships, shown in **Figure 9**, have very different management implications. Some people might hope for a relationship like that depicted by B in **Figure 9**, because this would mean that the maintenance or restoration of the ecological roles of predators requires only that they be present in low numbers. In contrast, other people with different values or goals might hope for a relation more like that depicted by C, in which the influence of predators is of little consequence at population levels below carrying capacity.

A final need is for greater understanding of the full range of food web effects by predators. Most studies of predator effects have focused on pairwise predator-prey interactions, thus creating the overly simplistic mind-set still held by many wildlife and fisheries managers. Most studies of indirect effects take this perspective only a step further by focusing on trophic cascades. However, as discussed previously, (*see Trophic Cascades and Generalized Food Web Theory*) trophic cascades are expected to mediate competitive interactions and influence the strength of bottom-up forces by altering production levels at the base of the food web. And as shown in the earlier examples, interactions of this nature can spread to seemingly unlikely species or areas of ecosystem structure and function. Little is known about such interactions, although several examples of long and complex chain reactions among species show that they can be quite important.

For the most part, food web and ecosystem dynamics have been studied by one of two approaches. The oldest of these involves descriptions of food web structure and estimating the transfer of materials and energy through their various linkages, the critical assumption being that flux rate reflects interaction strength. The fallacy of this assumption is evident in the fact that strong top-down forces necessarily reduce prey abundance to such low levels that the interaction may no longer be

apparent in a static food web. The second approach is to observe these dynamics directly by perturbing the system. Unfortunately, most experimental studies have been limited to processes acting on small spatial and temporal scales (for obvious logistical reasons) and to invertebrates and heterothermic fishes (for social and political reasons). Our general lack of understanding of the larger apex predators (especially large mammals) is due in large part to the almost complete absence of experimental evidence.

Creative approaches are needed to put the ecological influences of large apex predators into a dynamical context. The use of historical information and opportunities provided by “natural experiments” holds promise in this regard. The historical record is a rich source of information that has barely been utilized. Assessments of the wolf/moose/boreal forest system and the wolf/elk/temperate forest from tree ring analysis, and the sea otter-kelp forest system from faunal remains in Aleut kitchen middens illustrate the utility of this approach. Fortuitous change is another potential means of assessing the ecological roles of large apex predators. Studies by John Terborgh on the recently formed islands of Lago Guri, by Kevin Crooks and Michael Soulé on mesopredator release in urban habitat fragments, and by James Estes and John Palmisano on sea otters and kelp forests demonstrate the value of this approach. As these and other examples show, ecologists and resource managers must remain mindful of appropriate scales of time and space for both learning about predators and applying that knowledge to the conservation of biodiversity.

Glossary

Autotrophic successions These generate energy from internal processes (photosynthesis).

Climax community According to some theories of succession, the end result of succession in which successional change ends with a community that does not change and that is in equilibrium with the climate.

Disturbance Major alternations in vegetation due to events such as wildfires, hurricanes, landslides, and human clearing.

Heterotrophic successions Dependent on already fixed energy, such as the successional of communities associated with the decomposition of dead logs.

Individualistic view of succession The concept that succession is a consequence of species interacting with one another and their environment.

Primary succession Succession on newly exposed substrates such as a sandbar or rubble at the foot of a receding glacier.

Progressive succession Successions in which the dynamic changes are in the directions of increasing species diversity, structural complexity, greater biomass, and increased stability. Retrogressive successions are in the opposite directions.

Secondary succession Succession on existing substrate (soil) following a disturbance.

Succession The pattern of change expected in a community over time after a disturbance or after a new substrate has been exposed.

Introduction

Ecological succession is an ordered progression of structural and compositional changes in ecosystems toward an eventual stable condition. Primary successions are initiated on new substrates, such as a new volcanic island, a new sandbar in a river, or rubble fields at the foot of a receding glacier. Secondary successions involve the recovery of vegetation on established soils from land abandonment and from disturbances such as wildfires, hurricanes, or human alterations to vegetation. Other significant dichotomies used to categorize succession involve whether a given successional sequence is

1. Progressive (dynamically changing in the directions of increasing species diversity, structural complexity, greater biomass, and increased stability) or retrogressive (in the opposite directions).
2. Autotrophic (generating energy from internal processes) or heterotrophic (dependent on already fixed energy, such as the successional of communities associated with the decomposition of dead logs).
3. Autogenic (changing due to interactions from inside the system) or allogenic (changing in response to changes in external variables).

Ecological succession is an early concept in ecology and was essential in the early definitions of ecological communities. Although the basic concepts of succession are easily understood, debates about succession have led to considerable confusion and discussion. The mechanisms that drive ecological succession and its very existence as a natural phenomenon have been the subject of continual debate among ecologists. McIntosh (1985) identifies two contrasting views that typify traditional natural history and can also be found in current discussions of theoretical ecology. This dichotomy, which can be used to organize theories about ecological

succession, contrasts mechanistic explanations and organic (holistic) explanations of the causes of succession. For mechanistic theories about succession, known laws explain the actions of the individual parts of a system and the whole system is the sum of these parts and their interactions. In the case of organic or holistic explanations, the whole system, its existence and design, explains the actions of the parts. Mechanistic explanations are often considered as the more modern interpretation of succession, but these modern views may have been the first that developed and certainly developed as early as the organic views. Organic explanations of succession were most popular, at least in the US, between the 1920s and the early 1950s and have had a considerable impact on land use and conservation policies.

Organic Explanations of Ecological Succession

Organic explanations seek to understand succession in terms of the principles that operate at the level of the whole system. In the 1920s and 1930s, Clements and particularly John Phillips were ascribing to ecological communities the attributes of a superorganism – a highly organized and coevolved assemblage of plants and animals interacting in a dynamic system. The ecosystem concept had its roots in debates regarding the organization and dynamics of natural systems. It was Tansley's negative view of Clements' and Phillips' interpretation of the community as a superorganism that, in 1935, inspired his development of the ecosystem concept as an alternative to the organic term "community."

Clementsian Concepts of Ecological Succession

Between 1905 and 1935, Clements promoted a dynamic plant ecology built around a supraorganismic view of the ecological

community. At the time of their conception, Clements' ideas represented a significant emphasis on the dynamics of vegetation and were an important early attempt to develop a formal theory predicting the pattern and expected change in ecological communities. The underlying conviction was that evolution and internal interactions would produce a homogeneous regional climax vegetation or community of regular species composition. The development of this climatic climax community was ecological succession, which was viewed as the community analog of the embryological interactions that produce an organism. In this view, succession was typified by a progressive sequence of seral stages or seres, communities that sequentially replaced one another over time until the climax stage was reached. Successional development was the result of a set of processes:

1. Nudation – the creation of a bare area (or partially bare area) to initiate succession.
2. Migration – the arrival of organisms at the location.
3. Ecesis – the establishment of organisms at the location.
4. Coaction – the interactions, particularly competition, among the organisms.
5. Reaction (or facilitation) – the modification of the site by the organisms and the subsequent change in the relative abilities of the organisms to establish and survive.
6. Stabilization – the development of a stable community called the climax community.

Stabilization is less a process and more a consequence of the iterative reapplication of the migration, ecesis, coaction, and reaction processes until a stable community is reached. Clements' concept of the climax community was that there was only one stable vegetation type that was in equilibrium with the regional climate. Succession was the orderly, predictable, progressive, and linear development toward this climax community.

Application of Clementsian Concepts

The Clementsian succession paradigm had a pronounced effect on ecology in the US in the first half of the twentieth century (much less so in Europe), and it shaped many of the laws and policies on the use of public lands. Earlier ecologists developed some of these ideas, and others evolved over Clements' and associates' scientific careers. Important aspects in the Clementsian paradigm, many of which continue to be a part of natural land management today, are as follows.

Community-Level Management

The idea that one could use the state of ecological communities to evaluate their past and present conditions and to predict their future is a significant contribution of Clements and associates. Although it has been established by paleoecological studies that communities are not necessarily stable over century and millennial timescales, short-term changes and disturbances are often seen as changes in communities. Conservation groups often make considerable effort to preserve unique communities (as well as unusual or important species). Wildlife and endangered species management is often based on maintaining particular communities or habitat types appropriate to the survival of focal species of animal or plants.

Indicator Species Concept

Clements believed that the presence or absence of particular species could be used to assess the state of a community and its potential for agricultural conversion. For example, the presence of poisonous or distasteful plants on a range indicates overgrazing, the occurrence of certain species of Lupine (*Lupinus plattensis*) in a Nebraska prairie connotes a deep soil suitable for tilling and agriculture, and land with plants such as *Salicornia* might be so loaded with salt as to be unrecyclable. One could use indicator species to determine the past history of a landscape and to predict its future changes and potential uses.

The Climax Community Concept

The climax community is the community that is stable in a given climate condition and is the ultimate product of successional processes. Current vegetation maps, particularly for large regions, display the expected climax community or the potential natural vegetation expected in a region rather than the actual vegetation found there. Parks and wilderness areas are managed to maintain the natural climax community that is typical of the region. As an issue in conservation of diversity, often considerable effort is made to preserve unique communities (as well as species).

The Progressive Nature of Succession

Clements viewed succession as being progressive (moving in a positive direction) toward the climax community. The succession progressed toward more diverse, more stable, and more desirable communities. This is a concept associated with eighteenth-century intellectuals and tied to other concepts such as the divine design of natural systems and ideas about the balance of nature and of the antiquity of certain ecological communities. Whether from Clements or earlier sources, these ideas have a considerable influence on the esthetics of conservation in the valuation of wilderness and the assessment of the importance of preserving certain species rather than others.

Perhaps the most enduring legacy from Clements is his pioneering attempt to synthesize quantitative observations about succession into a unified theory. Even strong detractors of the details of Clements' concepts are still involved in understanding succession as a general phenomenon.

Alternative Organic Theories on Succession

Clements' theory is the most frequently presented organic succession theory, so much so that textbook writers often term Clementsian theory to be classic succession theory. However, all American and British ecologists did not accept these ideas. This rejection was certainly the case for ecologists from continental Europe. Some of these ecologists emphasized a more individual species-oriented mechanistic description of succession. Others shared an interest in the holistic causes of successional change but differed from Clements in significant details. Cowles, who, in 1899, was one of the first American ecologists to study ecological succession, characterized succession as "a variable approaching a variable." Succession was considered the change of a system perturbed away from – but

moving toward – an equilibrium that is itself changing. Cowles believed that the climax community was never reached. In 1935, Tansley contrasted Clements' climatic climax or monocl意思 theory with a polyclimax theory that had the climax vegetation of a region as a mosaic of local vegetation climaxes related to local conditions and disturbance history. In 1913, Cooper studied the forest succession on Isle Royale (Michigan) and found that the mature forest was a mosaic of patches of different ages and not the uniform climax community expected in Clementsian succession. He also believed that succession took multiple pathways and was not a linear progression of changes in seral stages. Similarly, in 1901, Cowles noted, "Succession is not a straightline process. Its stages may be slow or rapid, direct or tortuous and often they are retrogressive" (*Botanical Gazette* 31, 73–108, 145–182). Recognizing that there is and has been considerable difference in opinion among ecologists who use organic explanations of ecological succession, there is an even stronger contrasting of concepts between Clementsian succession and mechanistic explanations of ecological succession emphasized by some ecologists.

Mechanistic Explanations of Ecological Succession

Some of the debate about the nature of succession concerns the degree to which the vegetation can be arranged into communities that are natural units of biological organization. Introductions of modern biology or ecology texts often have diagrams of biological organization that illustrate an organizational hierarchy from cells to tissues to individuals to populations to communities, etc. Such progressions convey the idea that the community is a unit of organization as demonstrable at a level such as the existence of the liver or the spleen as an organizational unit is at some other level.

The American Gleason (in 1926) and the Russian Ramensky (in 1924) emphasized that vegetation was mostly the consequence of the chance arrival of species at a location and the subsequent interactions among the available species to produce the observed pattern of relative species abundance. These interactions did not produce distinct unit communities. The vegetation was believed to vary continuously with the changes in the underlying environmental conditions. According to this individualistic view of ecological succession, the process of succession was a consequence of species interacting with one another in the context of the environment to produce vegetation dynamics or successional change. Today, most ecologists subscribe to this individualistic view of ecological succession.

Descriptive Mechanistic Models of Succession

When one compares modern descriptive models of succession with the Clementsian model, it is apparent that there is a substantial difference in the spatial scale considered by the two schools. Clements' climax community was considered by him to be a phenomenon that occurred over large areas. This is evident from the fact that Clementsian succession proceeded toward a regional-scale climax. Also, the union of the climax community (vegetation) and associated animals was a biome of which there were thought to be only 13 in non-tropical North America. Clements believed that when the community in a given location was too small to have all of the species represented, succession might take different courses. However, he also believed that the succession processes he had described (nudation, ecesis, coaction, etc.) would still operate at these smaller scales.

In 1987, Pickett and colleagues produced a table of the mechanisms and causes of succession that can be compared directly with the earlier writing of Clements (**Table 1**). In this comparison, one sees that many of the processes deemed

Table 1 Clementsian succession processes compared with a mechanistic explanation of the causes of succession^a

<i>General causes of succession</i>	<i>Contributing processes of succession</i>	<i>Modifying factors</i>	<i>Clementsian succession analog processes</i>
Site availability	Coarse-scale disturbance	Size, severity and timing of disturbance, dispersion of species	Nudation and migration
Differential species availability	Dispersal	Landscape configuration, dispersal agents	Migration
Differential species performance	Propagule pool	Time since last disturbance, land use conditions	Migration and ecesis
	Availability of resources	Soil condition, topography, microclimate, site history	Ecesis
	Ecophysiology	Germination requirements, photosynthesis rates, growth rates, population differentiation	Coaction
	Life history	Photosynthesis allocation pattern, timing of reproduction, mode of reproduction	
	Competition	Hierarchy of competitive interactions, the presence of competitors, identity of competitors, within-community disturbances, predators, herbivores, resource base	
	Herbivory, predation, disease	Climate cycles, predator cycles, plant vigor, plant defenses, community composition, patchiness	
	Environmental stress	Climate cycles, site history, prior occupants	Reaction (in part)
	Allelopathy	Soil chemistry, soil structure, microbes, neighboring species	Not included as process

important by Clements (notably, nudation, migration, ecesis, coaction, and reaction) are also represented by a mechanistic explanation of succession, albeit with different names and differing emphases. The differences are most pronounced with regard to the importance of the reaction (facilitation). Certainly in many primary successions, the changes produced by one set of species appear necessary for the success of the next. For example, the rapidly growing willows (*Salix* sp.) that stabilize sandbars in rivers seem to be a necessary preamble to the success of subsequent species; the ability of alder (*Alnus* sp.) to symbiotically fix nitrogen increases the fertility of sites uncovered by receding glaciers; and the organic acids produced by blue-green algae, lichens, and mosses speed the breakdown of granite and the development of a thin soil to support grasses, herbs, and even trees in primary successions on granite outcrops.

However, some species appear to block the success of others and hold sites against species that might otherwise succeed them. In some secondary successions, all the species involved in the succession are present as seeds or other propagules from the initiation. In these cases, the familiar successional sequence of grasses and herbs yielding to shrubs and then to trees may reflect a difference in the rate of growth of individuals present from the start. Evolutionarily, it is difficult to explain why a species would evolve to help another take over a site it could otherwise occupy.

Connell and Slatyer (1977) developed a descriptive model of the succession processes based on a mechanistic

understanding of succession (Figure 1). They used the reaction/facilitation issue to frame three models of succession based on mechanisms of interaction (the facilitation model, tolerance model, and inhibition model). In Figure 1, the facilitation model is most like Clementsian succession as typically interpreted. The three models are different and have different implications for land management and particularly land reclamation. If one had the objective of restoring degraded landscapes, then one might speed the restoration by eliminating established species in the case of the inhibition model, but this would be ill advised in the facilitation model (Figure 1).

The Landscape as a Mosaic

In addition to an expansion of the facilitation concept associated with Clementsian succession, there has also been an emphasis on understanding the mosaic nature of vegetation. Historically, this emphasis derives from earlier concepts of cyclical succession (exemplified by the cyclical replacement series involving a forest canopy gap) and the polyclimax (the mature forest as a mosaic trees, gaps, and recovering gaps). Theories about the dynamics of landscape mosaics have been developed in forests to a significant extent, probably because, regardless of other sources of spatial heterogeneity, a forest canopy is a mosaic of tree crowns (Figure 2).

Starting with a small plot of land in a mature forest dominated by a single large tree, the large tree shades the

Figure 2 The forest canopy as a mosaic as seen in the fall colors of a mixed-wood forest, southern Quebec.

ground and reduces the survival of smaller trees and seedlings below. There may be a few smaller shade-tolerating trees that survive under the large tree, but these are strongly suppressed in their rate of growth. The large tree dominates the resources (light, water, and nutrients) that are available at the site and blocks other trees from growing at the location. When this tree dies, the forest floor (where there had previously been little chance of a young tree's survival) becomes a nursery for small seedlings and saplings. There is adequate light and other resources, and hundreds of small trees survive and begin to grow toward the canopy. As these trees grow, they begin to compete with one another. Some of the trees lose to more vigorously growing competitors. Eventually, one tree manages to win the race to be the local canopy tree and begins to eliminate the others. This represents the closure of the cycle, with a large tree again dominating the site. Over the course of time, this cycle is reinitiated by the death of the new dominant replacement tree. The implications of the cyclical nature of small-scale forest dynamics were clearly elucidated by Cooper in 1913 and by Watt in a classic paper in 1947.

The expected changes in the amount of living material (biomass) over multiple iterations of a gap generation and filling should create a saw-toothed shape curve. This curve drops abruptly with the death of a canopy dominant and then builds biomass as the regenerating trees grow, compete, and occupy the site (Figure 3, top). The distances between the teeth in the saw-toothed, small-scale biomass curve are determined by how long a particular tree lives and how much time is required for a new tree to grow to dominate a canopy gap.

Figure 3 Biomass dynamics for an idealized landscape. The response is from a relatively large, homogeneous area composed of small patches with gap-phase biomass dynamics. (Top) The individual dynamics of the patches that are summed to produce the landscape biomass dynamics. (Bottom) The landscape biomass curve rises (a) as all of the patches are simultaneously covered with growing trees. Next, local decreases in biomass are balanced by the continued growth of large trees at other locations and the curve levels at a maximum value (b). If the trees have relatively similar longevities, there is a period in which several (perhaps the majority) of the patches that comprise the forest mosaic all have deaths of the canopy-dominant trees and the curve decreases (c). Eventually, the local biomass dynamics become desynchronized (d), and the landscape biomass curve varies about some level (e). Reproduced from Shugart HH (1998) *Terrestrial Ecosystem in Changing Environments*. Cambridge, UK: Cambridge University Press.

The larger scale biomass dynamics (Figure 3, bottom) is a simple statistical consequence of summing the dynamics of the parts of the landscape mosaic. If there has been a synchronizing event, such as a clear-cutting or other disturbance, one would expect the landscape mosaic biomass curve to increase as all of its parts are simultaneously covered with growing trees (Figure 3a). If the trees over the area have relatively similar longevities, there is also a subsequent period when the deaths (and biomass) on plots where a canopy tree

happens to die are balanced by those on plots where large trees are still growing. During this period, the loss balances gain in biomass and the curve levels (Figure 3b). If there is sufficient synchronization in the saw-tooth curves of the component plots, this is followed by a period during which many of the pieces that comprise the forest mosaic all have deaths of the canopy-dominant trees (Figure 3c) and landscape biomass decreases. Over time, the local biomass dynamics become desynchronized and the biomass curve varies about some level (Figure 3d). This mosaic of repairing gaps with all different stages of recovery represented on the landscape can be considered as the mature forest.

The mature forest should have patches with all stages of gap-phase dynamics and the proportions of each should reflect the proportional duration of the different gap replacement stages. Whitmore (1982) believed that this was the expected pattern and process for all forests and asserted that forests of the world are fundamentally similar, despite huge differences in structural complexity and floristic richness, because processes of forest succession and many of the autecological properties of tree species, worked out long ago in the north temperate region, are cosmopolitan. There is a basic similarity of patterns in space and time because the same processes are at work.

Whitmore is referring to mosaic forest canopies as a consequence of gap replacement processes. The occurrence of such patterns has been documented for several different kinds of forests. The presence of shade-intolerant trees occurring in patches in mature undisturbed forest is another observation consistent with the mosaic dynamics view of mature forests. The scale of the mosaics in many natural forests is somewhat larger than one would expect from gap filling of single tree gaps, indicating the importance of the phenomena that cause multiple tree replacements. Also, relatively long records (approximately 40 years in most cases) of forest structure and composition indicate a tendency for the forest composition to fluctuate with species showing periods of relatively weak recruitment of individuals to replace large trees and strong recruitment in other periods.

Quantitative Mechanistic Models of Succession

A consequence of the recognition of the mosaic nature of vegetation and an emphasis on more mechanistic representation of the succession process has been the development of quantitative models that can predict changes in vegetation structure (Shugart, 1998). Several of these models simulate the successional dynamics by accounting for the birth, growth, death, and interactions with the environment for the hundreds of individual plants living on a small plot of land. The predictions of hundreds of these plots are then combined to obtain a prediction of the change in ecological landscapes. Because they simulate the fates of each of the millions of plants involved in a landscape succession, these models are called individual-based models. These models require considerable computation efforts but they can be solved relatively easily as a consequence of the increased computational power of modern computers.

An advantage of individual-based models is that the following implicit simplifying assumptions associated with other modeling approaches (e.g., the Markov process or differential

equation-based models) are not necessary: (1) The unique features of individuals are sufficiently unimportant to the degree that individuals are assumed to be identical and (2) the population is perfectly mixed so that there are no local spatial interactions of any important magnitude. Most ecologists are interested in variation in individuals (a basis for the theory of evolution and a frequently measured aspect of plants and animals) and appreciate spatial variation as being quite important. These assumptions seem particularly inappropriate for trees that are sessile and that vary considerably in size over their life span. This may be one of the reasons why tree-based forest models are among the earliest and most widely elaborated of this genre of models.

One group of individual-based models simulates the establishment, diameter growth, and mortality of each tree in an area the size of a gap left by the death of a canopy tree and are called gap models. Gap models can be used as an example of the more general individual-based modeling approach. In most gap models, calculations are on a weekly to annual time step. Early gap models were developed for a size unit (approximately 0.1 ha) approximately that of a forest canopy gap. Gap models feature relatively simple protocols for estimating the model parameters. For many of the more common temperate and boreal forest trees, there is a considerable amount of information on the performance of individual trees (growth rates, establishment requirements, and height/diameter relations) that can be used in estimating the parameters of such models. Gap models have simple, general rules for interactions among individuals (e.g., shading and competition for limiting resources) and equally simple rules for the birth, death, and growth of individual trees (based on the natural history of each species).

Gap models differ in their inclusion of processes that may be important in the dynamics of particular sites being simulated (e.g., hurricane disturbance, flooding, and formation of permafrost) but share a common set of characteristics. These latter characteristics involve an emphasis on the demography and natural history of plant species, relatively general rules for physiological tradeoffs among species, and an emphasis on the understanding of successional processes at the whole plant level. Each individual plant is simulated as an independent entity with respect to the processes of establishment, growth, and mortality. This feature is common to most individual tree-based forest models and provides sufficient information to allow the computation of species and size-specific demographic effects. Gap model structure emphasizes two features important to a dynamic description of vegetation pattern: (1) the responses of the individual plant to the prevailing environmental conditions and (2) how the individual modifies these environmental conditions. The models are hierarchical in that the higher level patterns observed (i.e., population, community, and ecosystem) are the integration of plant responses to the environmental constraints defined at the level of the individuals.

Succession and Biodiversity

Since the initial formulation of a progressive, holistic concept of ecological succession, there has been a tendency to

associate positive attributes to mature communities. Hence, there is an expectation for increasing successional age to be associated with increased biotic diversity. There are certainly ecological systems (notably many forest systems) that demonstrate this pattern, but there are other examples of ecological successions that show the highest levels of species diversity (measured as the number of species or by standard indices of diversity) at intermediate successional ages (e.g., shortgrass prairie in Colorado) or even at initial successional stages (e.g., boreal forests in areas of Canada). Succession on sand dunes on the coast of Queensland, Australia, has the highest species richness in shrubdominated communities at the beginning and end. The pattern of diversity in different successions seems to be an idiosyncratic consequence of the attributes of the participating species and the environmental conditions at a given location.

Biodiversity on Disturbed Landscapes

At the landscape level, the overall biodiversity can be related to the frequency and intensity of disturbance and there is evidence from both theoretical work and observations that an intermediate level of ecological disturbance can produce the most diverse landscapes (Huston and Smith, 1987). This occurs in part because disturbed landscapes have a mixture of species able to successfully occupy the differently aged patches created by the disturbance history of a given landscape. One

would generally expect highly heterogeneous landscapes to be more diverse. Disturbances also prevent particularly well-adapted species from occupying the entire landscape.

Grime (1979) developed a triangle based on three primary plant response strategies that can be used to develop rules that can be used to predict the proportions of each strategy (and associated life-forms) expected under a particular environmental regime. Grime recognized two types of external factors limiting the biomass of plants. The first was stress, involving the conditions that restrict plant productivity (shortage of light, H_2O , mineral nutrients, etc.). The second was disturbance, involving partial or total destruction of plant biomass (activities of herbivores, diseases, fire, frosts, etc.). These two external factors can operate independently so that there are four possible combinations of high or low stress and high or low disturbance.

Grime reasoned that the combined action of high stress and high disturbance created a condition from which the vegetation could not regenerate. Low-stress and low-disturbance environments would ultimately favor species that were able to compete effectively against other species (competitor strategy), high-stress and low-disturbance environments should be dominated by plants of species able to tolerate the particular stress (stress-tolerator strategy), whereas low-stress and high-disturbance environments should favor short-lived, fast-growing species (ruderal strategy). The general problem exemplified by Grime's work in the development of these primary plant strategies is one of identifying plant functional types. An essential basis of

Figure 4 Loss rates of species from different successional sequences. Reproduced from Shugart HH and Hett JM (1973) Succession: similarities of species turnover rates. *Science* 180: 1379–1381.

this as well as other functional classifications of plants is that of tradeoffs – the idea that, due to the underlying rules that derive from the species physiology and natural history, a single species cannot simultaneously be the best as a stress tolerator, a competitor, and a ruderal species.

The Gain and Loss of Species with Succession

One can view the richness of species on a parcel of land with the same disturbance history as a consequence of the gain and loss of species. The gain of species involves factors such as the migration and establishment of species (or the species gaining sufficient abundance or size so that it can be sampled). There has been debate as to whether the gain of species at a site over succession is a consequence of the different species present at the site growing and developing at different rates or is actually due to species establishing themselves in an ordered sequence. The succession is a consequence of different growth rates of an initial inoculum of seeds of all the species involved germinating and growing at different rates and is sometimes called the initial composition model (Egler, 1954). The idea that one set of species is added to the community after a previous set has modified the site and lost the site has been termed the relay floristics model (Egler, 1954). To separate these two models, a particular succession study has to be sampled intensively enough to actually detect all the species at a location, which rarely occurs. Considering a wide range of successions of plant communities, animals associated with succession, and heterotrophic successions (such as the progression of changes in a decaying log), one finds that the appearance of species with abundances sufficient to be counted varies with the particular collection of species and with the changes in the physical environment associated with the succession.

The loss of species from successional communities tends to be somewhat more regular in its pattern of variation. Considering a wide range of communities (both autotrophic and heterotrophic successions), one finds that the rate of species local extinction through succession tends to decrease logarithmically over successional time. Successional sequences are often sampled and reported using a more or less logarithmic

sampling regime (e.g., communities in a successional study might be sampled at 1, 2, 5, 10, 17, 35, 60, and 100 years). This reflects the pattern that one tends to sample successional sequences using designs where a proportion of the species in a site of a given age were found in the younger sites. **Figure 4** illustrates this pattern for five different successional sequences in different locations. The initial loss rates of species are on the order of approximately 10% of the species found on a plot disappearing each year. In the later successional stages, this decreases to less than 0.1% species lost per year (**Figure 4**). Because this pattern occurs across a wide range of successional sequences, this does not appear to be a consequence of the later successional species living longer (as is often the case in forest successions).

Glossary

Biophilia The innate tendency to focus on life and lifelike processes, or the “innately emotional affiliation of human beings to other living organisms” (Wilson, 1984). According to Wilson, we humans have an affinity for the natural world that has evolved over millennia and is part of our genes, just like our tendency to be territorial or to protect our young.

BLMV Bureau of Land Management Lands Visitation = (Total number of annual visits to all Bureau of Land Management lands in the USA)/(Total population of the US).

Duck Stamps Federal Migratory Bird Hunting and Conservation Stamps, pictorial stamps produced by the US Postal Service for the US Fish & Wildlife Services as the federal licenses required for hunting migratory waterfowl.

NFV National Forests Visitation = (Total number of annual visits to all national forests in a nation)/(Total population of a nation).

NPV National Parks Visitation = (Total number of annual visits to all national parks in a nation)/(Total population of a nation).

SPV State Parks Visitation = (Total number of annual visits to all state parks in a nation)/(Total population of a nation).

Videophilia The new human tendency to focus on sedentary activities involving electronic media (Pergams and Zaradic, 2006).

Virtual nature Nature experienced vicariously through electronic means.

Why We Care

The greatest threat to conservation and the environment may be more subtle than bulldozers and chainsaws. Our review of studies on attitudes toward the environment suggests that direct contact with nature, especially as children, is the most critical influence on later attitude toward the environment (Zaradic and Pergams, 2007). Family vacations and spending time with family and other mentors outdoors is cited as a major influence on later environmental attitude and activism (Chawla, 1998). Yet for the period 1987–2003, *per capita* visits to national parks (NPV, America’s iconic family nature vacation) have steadily declined (Pergams *et al.*, 2004; Pergams and Zaradic, 2006), with this trend continuing today (Pergams and Zaradic, unpublished data). Moreover, most long-term trends point to a general and fundamental shift away from people’s participation in nature-based recreation with reliable long-term *per capita* visitation measures of nature recreation peaking between 1981 and 1991, declining approximately –1.2% per year, and totaling to date 18–25% (Pergams and Zaradic, 2008).

This declining trend in nature-based recreation is of enormous importance. Kellert (1996) describes human cultural learning and experience as exerting a fundamental shaping influence on the content, direction, and strength of people’s nature-related values. Similarly, it has been found that environmentally responsible behavior results from direct contact with the environment (Hungerford and Volk, 1990) and that people must be exposed to natural areas as children if they are to care about them as adults (Duda *et al.*, 1998). Extended periods spent in natural areas, especially with a mentor, seem to create the most environmentally responsible behavior (Matthews and Riley, 1995) and increased involvement in biodiversity conservation (Chawla, 1998). Moreover, as

today’s adult role models spend less time in nature, this generation of children is also likely to follow suit (Louv, 2006). Accordingly, the authors think it probable that any major decline in the value placed on natural areas and experiences will greatly reduce the value people place on biodiversity conservation.

Successful stewardship of the environment depends on recognizing our impact and interactions with nature. The less time we spend in nature, the less likely we are to recognize our human impact and respond ecologically and effectively. As global population grows, so does the need for and extraction of natural resources and the impact of humans on the planet. Humans are getting to a point in resource needs and global impact at which efficient use of resources is increasingly important. Rising CO₂ and global warming, overfishing of the oceans, air pollution and declining air quality concerns, pesticides detected in the most remote reaches of the wild, together form a plethora of indicators of our ability to impact the planet on a grand scale. Paying attention to these indicators (the canaries in our global coal mine) is the key to successful conservation stewardship and to provisioning the human species with clean water, air, and food in the face of global change.

Spending substantial time in nature is a selfish act in the best sense of the word; it satisfies our human–animal longing for multisensory interactions with “other,” it feeds our need to belong to a greater context beyond self, and it serves the individual and collective species purpose of increasing our survival. We humans, as part and parcel of the machinery of nature, are exquisitely designed through the process of evolution to sense, perceive, and respond to natural inputs. We, as collections of specialized receptors and integrative neural machinery replete with large cerebrums and opposable thumbs, are uniquely suited to attend and respond to changes

in the natural environment – as long as we are paying attention.

Conservation in the way the term has historically been applied may be outdated and inadequate. Lands set aside, sequestered separate from human impact, the outdoor equivalent of dusty museum dioramas, can ultimately only capture a small portion of the landscape and of the planet's biodiversity. There are few if any places on earth that are untouched by human use or impact. Whether it is pesticides traveling on the wind or acid rain, wildlife vectors transporting human-manufactured compounds, or transoceanic travelling trash, we have left an impression on the globe. Even the most wild and protected landscapes are at the mercy of wind and rain carrying compounds from the more civilized and heavily impacted corners of the globe.

Moreover, even if we managed to conserve, in this instant in time, all the land required to fulfill our conservation goals, without the political and social will to maintain that status these lands would not stay conserved for long. As human populations continue to grow, practice consumerism, and act unsustainably, so will pressure to exploit wild lands for their resource value. Conservation and nature stewardship must compete with all other human priorities. Fiscal and development decisions are made in the broader context of human priorities such as food, water, and housing security. Where nature stewardship falls on the scale of human priorities depends on providing for basic human needs while maintaining the interconnection with nature, the ultimate source.

Just as we track conservation goals and environmental indicators, the key to conservation's future may be tracking trends in human behaviors and attitudes regarding nature. The goal of this type of tracking is to examine trends and behaviors relevant to creating value in and connection to nature and the environment. The more interactive and prolonged the nature exposure, particularly when facilitated by a mentor, the more likely a higher degree of connection to nature will result. Further research is required to determine the duration, frequency, intensity, or wildness of the nature "dose" needed to instill an environmental ethic. Is viewing nature online half or one-tenth as effective as seeing that image live? How does watching a bird at a birdfeeder compare to spotting a bird on a woodland walk? There is likely to be a spectrum of outdoor activities, from those that occur outdoors but have very little to do with nature (such as a football game) to those that represent almost complete immersion in wild nature (such as solo wilderness backpacking). If the goal of tracking or encouraging nature exposure is to produce conservation ethics, then it is likely that a camping trip or a walk in the woods is a more reliable indicator of nature exposure than field hockey or a softball game. In the absence of more detailed research, determining the activities that are most relevant to instilling an environmental ethic requires keeping in mind the goal of these nature experiences: creating connection to the type of biodiversity and landscapes we would like to conserve.

Finally, in tracking trends in human behavior, it is important to remember that intentions do not necessarily translate to action, as is clear after every New Year's Day in the USA, when resolutions often fall by the wayside of habits. Therefore, surveying intentions of spending time in nature or

purchases made related to nature recreation is not the same as actual time spent in nature. Buying a fishing pole that sits in the hall closet is fundamentally a different experience than going fishing. Wearing a fleece jacket and carrying a water bottle to school is not equivalent to roughing it in the outdoors. In choosing activities as indicators of environmental ethics, it is important to keep in mind that ultimately, actual experiences with nature are required to develop a later conservation ethic.

Behind all threats to biodiversity and the environment is our perceived value of and connection to nature. The basis of all political and social will for conservation is the value we place on nature. Whether motivated by aesthetics, spiritual ideals, or self-preservation, how connected we feel to nature and how much we value nature will determine the decisions we make and priorities we set regarding nature stewardship.

Biophilia Replaced With Videophilia

Historical Trends

The downtrend in US NPV was first identified in 2004 and then compared with changing cultural trends in 2006 (Pergams *et al.*, 2004; Pergams and Zaradic, 2006). After many decades of status as the iconic American family vacation, it was not until the late '80s that the popularity of NPV began to decline. So from 1939 (the start of available data) until 1987, for 50 years NPV was an increasingly popular American pastime. Popularity is measured in *per capita* attendance; in other words, attendance at national parks was increasing above that which might be expected due to population growth alone. This is important because conservation and nature stewardship decisions are made in a competing market of interests. Maintaining the same number of visitors as the US population grows is in effect losing market share, in the same way that maintaining the same number of vinyl record sales as the population grows is an example of losing market share to other forms of music media. The steadily increasing popularity, measured as *per capita* NPV between 1939 and 1987 occurred in spite of many social and economic upheavals during that time frame, including recession, depression, World War II, changing demographics, the rise of interstate travel, innovations, and inventions. The period after 1987 is equally remarkable for its steady decline in *per capita* visits (Figure 1(a)). Somehow, something shifted after 1987 that impacted the popularity of NPV like no cultural, social, or economic shift in the 50 years prior.

Examining the Decline

National parks represent a national-scale measure of nature recreation. The decline in this very popular activity suggests a national, social change in nature recreation. To discover the cause of the decline, a suite of potential explanatory variables with logical links to park declines were compared with park visitation data to examine overall and percent year-to-year change in trends. Comparisons required annual, national data, extending back to at least 1987, the start of the decline.

Figure 1 (b) *Per capita* US national park attendance from 1939 until 2003 is graphed in black. In green is a linear regression calculated using park attendance between 1939 and 1987; and in blue, from 1988 until 2003. (a) The attendance portion of the graph from 1988 until 2003 in the dashed box is expanded to show both the actual attendance data (black) and the multiple linear regression model (red) of four entertainment media variables and oil prices. Reproduced from Oliver RW, *et al.* (2006).

Variables were considered significantly correlated if both overall and Spearman correlations of percent year-to-year changes were significant; significantly correlated variables were further combined in a stepwise multiple linear regression model to attempt to explain and predict the decline. Comparing the year-to-year percent difference removed the possible effects of heteroskedasticity (similarity of trending time series) alone causing the significant result.

In Pergams and Zaradic (2006), 13 variables that might impact park attendance and for which the authors have data were compared with NPV data. Those variables included factors that might impede people's ability to get to the parks, potentially negative experiences at the parks, some alternative nature recreation trends, and finally the increase in electronic media use. The variables representing factors which could impact people's ability to get to the park were: oil prices

(proxy for the price of gas), number of vacation days, and median family income. A potentially negative experience at the park due to overcrowding or park upkeep was measured by evaluating funding for national parks and park capacity at the 10 most popular parks. Modern alternative nature venues were evaluated by using foreign travel trends as a proxy for eco-tourism and thru-hiking of the Appalachian Trail as a proxy for extreme outdoor recreation. Finally, five electronic media variables were used to measure various types of modern media recreation: hours spent watching TV, home movies, movies in theatres, video games, and the Internet.

Of the variables considered, increased use of video games, home movies, theatre attendance, and Internet combined with inflation-adjusted oil prices explains most of the 16-year decline in *per capita* US NPV (linear regression model, $r=0.975$, adjusted multiple $r^2=0.925$, $SE=0.015$, $F=37.800$, $p<.0001$,

Figure 1(b)). Other factors were either not significant or did not add to the explanatory value of the model. For example, federal funding in inflation-adjusted dollars rose during that period, the most popular parks continued to increase in visitor capacity through the mid-1990s, and the aging baby boomers were still of prime family vacation age at the time (Pergams and Zaradic, 2006).

Videophilia

Of course, correlation alone does not demonstrate causation. However, a raw r value of 97.5% in a multiple linear regression denotes a huge amount of explanatory power. Moreover, given the logical link and the extremely tight relationship between the rise of these potentially causal factors and the decline in park visitation, either the relationship is causal or both the rise in electronic media and the decline in park visitation are closely tied to some greater social shift in values and recreation choices. Finally, some of these electronic media choices essentially came into existence around the time the park visits began declining. The average person in the USA went from spending 0 h year⁻¹ on the Internet in 1987 to spending 174 h year⁻¹ on the Internet in 2003, and from spending 0 h year⁻¹ playing video games in 1987 to spending 90 h year⁻¹ in 2003 (Pergams and Zaradic, 2006). Again, home video games and Internet use essentially came into existence around the time park visitation started declining, and this increases the likelihood of causality to some extent. Altogether the average person in the USA spent 327 more hours/year on these entertainment media in 2003 than he or she did in 1987, an incredible increase in time (Pergams and Zaradic, 2006). Interestingly, television did not appear to have the same dramatic impact in relation to park visits. It appears that there is something particularly compelling about the personalized, immediate gratification of current electronic media entertainment. Most recently, baby boomers were found to average the most daily screen time at just more than 9.5 h/day, but all other age groups were strikingly similar, at roughly 8.5 h/day (Hess and Brill, 2009).

This declining trend in nature-based recreation is of enormous importance. We may be seeing evidence of a fundamental shift away from people's appreciation of nature ("biophilia," Wilson, 1984) to "videophilia," defined as "the new human tendency to focus on sedentary activities involving electronic media."

Electronic media, in addition to taking up our time in absolute terms, is essentially a sedentary activity, whereas NPV is much less so. The increase in sedentary lifestyles has been suggested as an explanatory factor for the rise in obesity in the USA (Flegal *et al.*, 2002; Skidmore and Yarnell, 2004). Time spent involved in sedentary media activities has also been implicated in reducing the amount of time spent in physical activity (Skidmore and Yarnell, 2004; Fotheringham *et al.*, 2000; Utter *et al.*, 2003). It seems likely that in addition to taking up our time, the increase in sedentary electronic media more broadly impacts recreation choices. National parks are losing their market share, whether directly to time spent on electronic media or indirectly to recreation choices favored by sedentary, electronic media consumers. Either way, this does

not bode well for our society's long-term connection to nature and support of biodiversity conservation.

National and International Trends in Nature Recreation

How Widespread Is the Decline?

After publication of the national parks and videophilia research, there were some suggestions that perhaps the national park trends were due to factors limited to the US park system, such as reduced interpretive staff, changes in admission fees, or park use structure. Perhaps other nature areas that allowed alternate recreation (such as Forest Service lands that allowed all-terrain vehicle (ATV) use) were successfully outcompeting national parks for market share. Sceptics also pointed to the rise in outdoor adventure goods sales as indicators of increased nature recreation.

To determine how indicative the decline and pattern in NPV is of broader trends in nature-based recreation, Pergams and Zaradic (2008) identified 16 long-term time series assessing various types of nature-based recreation. As before, data series had to represent nationwide long-term annual measures of actions rather than intentions and had to stretch as far back as 1987, the start of the decline.

People, Places, and Activities

The nature recreation data series fell into three categories, places, activities, and people: annual visitation measured at various nature places, frequency of participation in nature-based recreation activities, and market surveys of the American people regarding natural lands visits and nature recreation to independently verify the other lines of data. By using a variety of approaches to evaluate nature-based participation, Pergams and Zaradic (2008) could determine the robustness of their initial evaluation. US visitation measures included data from: NPV, SPV, Forest Service, and Bureau of Land Management (BLMV). Measures of nature recreation activities included national rates of hiking, backpacking, and camping, as well as hunting and fishing license data. National survey data included measures of annual rates of camping, hiking/backpacking, and visits to state and federal parks. In addition to trends in the USA, Pergams and Zaradic, 2008 were able to gather NPV data from Spain and Japan.

Rather than an anomaly restricted to national parks, the results of the analysis suggest a persistent and pervasive decline in *per capita* nature recreation (Pergams and Zaradic, 2008). National survey data corroborate declines detected in natural lands visitor data at approximately the same rate over the same time frame (Figure 2). Long-term nature visitation data was highly significantly correlated among the various park visitation variables. Long-term nature use data sets (greater than 50 years) suggest the typical decline in *per capita* nature recreation is -18% to -25% so far, starting between 1981 and 1991, and is declining at -1.0% to -1.3% per year (Figure 2 and Pergams and Zaradic, 2008). These similarities and the highly significant correlation among various public land visitation variables corroborate a general longitudinal

Figure 2 Annual *per capita* visitation to various US and international public lands. Included are US national parks (variable NPV, range of time series 1939–2006, $N=68$), US state parks (SPV, 1950–2003, 24), US national forests (NFV, 1939–2002, 61), US Bureau of Land Management sites (BLMV, 1982–2005, 20), Japanese national parks (Japan NPV, 1950–2005, 56), and Spanish national parks (Spain NPV, 1996–2006, 11). Linear regressions for declines from identifiable peaks in NPV (1987) and Japan NPV (1991) are represented by lines and equations. Reproduced with permission from Pergams ORW and Zaradic PA (2008) Evidence for a fundamental and pervasive shift away from nature-based recreation. *Proceedings of the National Academy of Sciences, United States of America* 105: 2295–2300.

decline in visitation to natural areas rather than an isolated decline in US NPV (Pergams and Zaradic, 2008).

International Trends

Moreover, the trend in declining nature use could well extend beyond US political and cultural boundaries. Japan's 56 years of *per capita* NPV data was among the most highly correlated with all of the long-term US public land data, in both untransformed and difference model comparisons (Pergams and Zaradic, 2008). Spain's national park data was limited to post-1995, well after declines detected in most of the other longer-term data sets. As compared with both the USA and Spain, the Japanese visit their national parks much more frequently (more than three times a year on average at peak, as compared with just more than once a year for Americans at US national parks and approximately once every 4 years for Spanish citizens in Spain, Figure 3). Japanese NPV trends are extraordinarily similar to those for Americans in US state parks (Figure 2, Pergams and Zaradic, 2008, $\rho=0.928$, $p<.0005$); perhaps due to Japan's smaller size, Japan's national parks are more readily accessible.

The similarity between visitor patterns at Japan's national parks and US parks suggests that the cause of the decline is also similar. Of the various suggested causes for the US decline in nature recreation, very few would also hold true for simultaneous declines in Japanese nature recreation, with the exception of our common fascination with videophilia.

Nature Places Declining in Popularity

United States National Forest data and US national park data stand out among the most highly correlated time series for both the high overall correlation and the length of these two data sets (Pergams and Zaradic, 2008, $\rho=0.931$, $p<.0005$, $N=61$). Discounting the probably inflated National Forest visitor (NFV) data in the mid-1990s, both US national park and NFV show steady increases for 50–55 years before a considerable decline. Even given the differences in counting methods and missing years of visitor data in the late 1990s, it is remarkable that the last time the national forests saw *per capita* visitors as low as 2002 was almost 40 years earlier (Figure 2).

Most US nature exposure as detected in our data sets is through state park visitation (SPV) (Figure 3, on average three

Figure 3 Annual *per capita* participation for all 16 of the nature recreation variables included in any part of the authors' analysis. The figure is meant merely to compare relative *per capita* participation in the recreation choices the authors address.

times a year per American at peak, as compared with approximately one visit a year at peak for national parks or forests). Although nationally reported numbers for SPV are sporadic, the last 15 years of data on SPV suggest a decline similar to that seen in Japan's national parks (approximately -19% total and -1.3% annual). The decline in BLMV properties, although a much smaller component of US nature exposure (Figure 3), is highly correlated with both the overall trend and year-to-year declines in SPV (Pergams and Zaradic, 2008).

Survey the People

US public surveys from two market survey sources independently corroborate the decline reported from park visitor counts (Pergams and Zaradic, 2008; Figure S2). The range of US data included in our comparisons covers all public nature spaces for which national visitor use is available. The fact that all of these US public land time series (as well as Japan's) are among the most highly correlated (Pergams and Zaradic, 2008) suggests that public nature spaces in the USA and Japan are generally similarly responding to changes in nature participation (Figure 2). Moreover, the many significant short-term correlations in declining public land use in the USA and Japan (Pergams and Zaradic, 2008) suggest that there has been a general national and potentially international fundamental shift in people's participation in nature recreation over the last 20 years.

Camping data from two market survey sources independently corroborate the decline reported from park visitor counts (Pergams and Zaradic, 2008). The Mediamark camping survey questions refer specifically to camping within national parks

and forests (mmCampingNP/NF) or state parks and forests (mmCampingSP/SF). Furthermore, the decline in annual camping as detected by both of the Mediamark surveys was significantly correlated with the decline in NPV. Mediamark survey results for declining camping in national parks and forests were also significantly correlated with SPV (Pergams and Zaradic, 2008). The consistency between survey results and the trends in public lands visitors suggest that declines detected in the visitor data are not due to changing counting methods by the parks, but rather represent actual visitor declines.

Nature Activities Declining in Popularity

Camping is the largest recreation component of the *per capita* pie chart, a choice for approximately one in five Americans, more popular in *per capita* participation than hunting or fishing (Figure 3). As such, a trend of fewer and fewer Americans going camping is especially notable. Along with the Mediamark annual surveys, data from Statistical Abstracts surveying the frequency of camping in any venue also suggests a decline since 1987 (Pergams and Zaradic, 2008). This survey and visitor data together suggest that, rather than a change in recreation venue, we are detecting a real shift away from nature as a recreation choice.

The range of *per capita* participation in all variables is very large: each Japanese individual visits their national parks on average 2.747 times per year (351 million visits total), whereas each USA individual finishes the Appalachian Trail on average 0.000002 times per year (<700 visits total), or six orders of magnitude less (Figure 3). It is therefore important to realize that although all of these trends are of interest, some of them involve many more people than others, and are much more important when discussing national or global trends. The only

counter trends to the decline in nature recreation come from a small minority of hikers and backpackers. Survey data suggest that hiking in all venues increased from 0.08 *per capita* participation in 1987 to 0.098 in 2002. Most of the hiking and backpacking participation survey results were significantly negatively correlated with the general decline in nature recreation (Pergams and Zaradic, 2008). Rather than attracting a new sector to nature recreation, the small but steady growth in the hiking and backpacking market may reflect individuals who were previously campers choosing day hikes instead of overnight camping trips.

Fishing and hunting were next in popularity after camping (Figure 3). They are closely correlated (Pergams and Zaradic, 2008) and both increased in popularity until the early 1980s. Hunting has managed to hang on to most of its market share since its 1983 high; however, fishing has experienced a considerable *per capita* decline (–25% from its 1981 peak, an average of –1.0% a year). This may be related to various overfishing and pollution issues decreasing access to fish populations, contrasted with exploding deer populations (which are largely anthropogenic effects). The decline in fishing is highly significantly correlated with the decline in visitors to US public lands since 1987 (Pergams and Zaradic, 2008). The US duck stamps time series is a subset of the much larger recreation category of US hunting licenses (*per capita* participation 0.005 vs 0.120, Figure 3). Duck hunting regulations are sometimes more complex, often have higher equipment costs (decoys, boats, and dogs), and often require access to relatively rare habitat (wetlands) than many other forms of hunting (Stephens, 2007). This may in turn relatively deter recruitment of young duck hunters (Babcock, 2007). We would add as conjecture that although the number of ducks in the USA has only recently increased (e.g., +14% in 2007; Ducks Unlimited, 2007), the number of deer has been exploding for a long time (Stromayer and Warren, 1997).

Pervasive Decline in Nature Recreation

In conclusion, all major lines of evidence point to a general and fundamental shift away from people's participation in nature-based recreation with most reliable long-term *per capita* visitation measures of nature recreation peaking between 1981 and 1991, and declining at about –1.2% per year, and total to date 18–25% (Pergams and Zaradic, 2008). In addition, the cultural shift away from recreation in nature appears to extend outside of the USA to at least Japan. Our research suggests that the root cause is likely to be videophilia. Other factors may be responsible, but they would have to be large enough in scale and potentially international in impact, as well as timely enough in instigation, to generate this type of shift across the USA and potentially around the globe. Regardless of the root cause, the evidence for a pervasive shift away from nature-based recreation is clear.

Implications for Health and Childhood Development

Direct, Indirect, and Vicarious Nature

Declining nature experiences for people across the USA and potentially internationally is likely to have broad implications

for conservation. On the surface, declining *per capita* visits could decrease impact on natural areas and in that way seem beneficial. However, decreasing affinity for nature areas corresponding to increasing videophilia seems likely to present much greater long-term costs in loss of the constituency of support for conservation.

Teachers, environmental education, and exposure to nature through other venues (such as reading about nature) are credited with influencing environmental sensitivity, but to a much lesser degree than direct actual experience of natural areas (Chawla, 1998, 1999; Kahn, 2002; Kellert, 2002; Duda *et al.*, 2003; Wells and Lekies, 2006). Similarly, direct sustained contact with nature best cultivates children's environmental knowledge and concern (Vaske and Kobrin, 2001; Fisman, 2005). Direct experience with nature appears to uniquely effect childhood development as compared with other types of nature encounters (Zaradic and Pergams, 2007).

Kellert (2002) describes three modes of experiencing nature: direct, indirect, and vicarious. Direct experience involves actual physical contact with natural settings and nonhuman species. This is the spontaneous play in a forest, creek, neighborhood park, backyard, or even vacant lot. Although these settings are impacted by human manipulation to some degree, they function largely independently of human intervention. Indirect experience of nature involves physical contact but in a much more controlled and restricted setting. Examples include zoos, nature centers, aquariums, natural history and science museums, and domesticated animals such as cats and dogs. Vicarious experience of nature occurs in the absence of actual physical contact with the natural world. Nature in this form ranges from stylized and symbolic art to photographs, videos, and virtual webcam tours of natural areas.

A comparative review by Kellert (2002) suggests that of the three modes of contact, direct experience with nature plays the most significant role in cognitive and evaluative development. Direct experience of nature offers a multiplicity of sights, sounds, smells, and tactile stimuli shifting continuously in space and time. The spontaneity and complexity of these sensory experiences engage a wide range of adaptive and problem-solving responses, requiring alertness and attention (Sebba, 1991). In contrast, the more structured, indirect experiences of nature do not require the same level of spontaneous engagement and do not exert the same types of long-term developmental impacts on children (Kellert, 2002; Pyle, 2002). Similarly, Wells and Lekies (2006) found that direct contact with "wild" as compared with "domesticated" nature before age 11 is a particularly potent pathway to shaping environmental attitudes and behaviors in adulthood. Indirect experiences may exert the greatest positive effect in conjunction with direct encounters in familiar natural settings (Kellert, 2002). The least sensory engaging and spontaneous type of nature contact, vicarious experience through an electronic outlet, is becoming more prevalent. More families live in or near urban settings with more time committed to wage earning (Duda *et al.*, 2002). Internet, video game, and home movie use continues to increase dramatically as direct contact with nature via outlets such as national parks decreases (Pergams and Zaradic, 2006, unpublished data). What are the long-term impacts of this trend for childhood development and conservation?

A Sedentary Society

Increasing time spent in sedentary indoor media activities has been implicated in the decline in time available for outdoor physical activities (Skidmore and Yarnell, 2004; Fotheringham *et al.*, 2000; Utter *et al.*, 2003). An increasingly sedentary lifestyle in the USA is one of the explanatory factors in the rise in obesity (Flegal *et al.*, 2002; Skidmore and Yarnell, 2004). Frequency of being overweight and obese in US children older than 6 years and adolescents has doubled in the last two to three decades (Deckelbaum and Williams, 2001). Moreover, the spread of this behavior is resulting in similar doubling rates of obesity in developing countries (Deckelbaum and Williams, 2001). Even younger children are at risk because of this increasingly sedentary lifestyle, with more than 22 million children younger than 5 years of age overweight across the world (Deckelbaum and Williams, 2001).

Adult activity choices are significant for childhood development because children often depend on adults both for access to nature and as role models for recreational choices. Dong *et al.* (2004) provide an index of how much energy we currently spend on various activities during a 24-h day in our sedentary society. In 1992–1994, 7515 adults (weighted to be representative of the contiguous 48 states) were surveyed to create a detailed report of each activity performed in the previous 24 h. An energy expenditure index was created by multiplying duration and intensity of each activity by each individual and summing across all individuals. The top five ranked activities (representing 42.9% of all energy expended) are: driving, office work, watching TV/movie, childcare, and activities performed while sitting quietly. “Watching TV/movie, home or theater” and “activities performed while sitting quietly” (presumably including time on the Internet and playing video games) were together 14.4% of the total. The study was not designed to compare indoor versus outdoor activities, but it is still interesting that the two clearly outdoor recreational activities (“fishing and hunting” and “gardening”) were together only 1.5% of the total, and ranked 22nd and 27th, respectively. Given the activity choices adults are making, it should be no surprise that children are also spending less time in outdoor recreation as compared with time in front of a video screen.

Children and Videophilia

American Academy of Pediatrics guidelines recommend 0 h/day of screen time for children less than 2 years old and ≤ 2 h/day for older children. The guidelines also recommend that there be no electronic media at all in young children's rooms. In contrast, in a 2003 survey of 1000 individuals, parents of young children aged 0.5–6 years, Rideout *et al.* (2003) had a number of startling findings. In a typical day, 43% of children <2 years old watch television every day, and 26% have a television in their bedroom; 68% of children <2 years old spend >2 h a day using screen media. The larger sample (children aged 0.5–6 years) used screen media a little under 2 h/day. Almost all homes (95%) with children 0.5–6 years old had at least one VCR or DVD player, and 27% of children had one in their bedroom. On average, these children spend 40 min/day watching home movies, with 25% watching

videos every day. Video games still seem to start a little later, but by age 4–6, 50% of children play them, and 25% play several times a week or more, with an average time played of a little more than 1 h/day. These 2003 values are probably doubled or tripled now.

Children and the Natural Environment

Research has recently begun to explore children's relationships to the natural environment. Children younger than 13 years living in the USA reportedly spend on average only about half an hour of unstructured time outdoors each week, consisting of gardening, boating, camping, picnicking, pleasure drives, walking, and hiking (Hofferth and Sandberg, 2001). Bartlett (1997) describes behavioral and emotional problems as a result of lack of opportunity to play outside. Hüttenmoser (1995) found that 5-year-old children limited in playing outdoors by automobile traffic exhibited poorer social, behavior, and motor skills and had fewer playmates than children not so limited. Grahm *et al.* (1997) found that children attending a day care facility surrounded by orchards, pastures, and woodlands (and where the children went outdoors every day regardless of weather) had better motor coordination and greater attention capacity than did children who attended an urban day care center surrounded by tall buildings. Wells (2000), in one of the few studies to employ a longitudinal design, found that children who moved to housing with more nature nearby tended to have higher levels of cognitive functioning than children who moved to housing with less nature. Taylor *et al.* (2001) found that activities in green settings tend to lower the symptoms of children with attention deficit disorder (ADD). Taylor *et al.* (2002) examined the effect of nearby nature on girls aged 7–12 years living in Chicago public housing. The relative naturalness of window views was predictive of the girls' self-discipline, as defined by ability to concentrate, inhibit impulses, and delay gratification.

Wells and Evans (2003) interviewed 337 rural third to fifth graders to determine whether vegetation near their homes provided a buffer to stressful situations such as family relocation, being picked on or punished at school, or being subject to peer pressure. The children's emotional well-being was assessed by both the children themselves and their parents. Stressful life events had less impact on psychological distress under “high nature” conditions than under “low nature” conditions. This buffering appears to be greatest for those at most risk: those experiencing the highest levels of life stress.

Early TV and ADD

Christakis *et al.* (2004) applied logistic regression to the National Longitudinal Survey of Youth, containing data for some 2600 children at ages 1 and 3. The hypothesis tested was that early television viewing (at ages 1 and 3) is associated with attentional problems at age 7. Children watched an average of 2.2 h (standard deviation (SD): 2.91) of television per day at age 1 and 3.6 h (SD: 2.94) of television per day at age 3. They corroborated the hypothesis even after controlling for a number of potentially confounding factors, including prenatal

substance abuse, gestational age, maternal psychopathology, and socioeconomic status. A 1-SD increase in the number of hours of television watched at either age 1 or age 3 was associated with a 28% increase in the probability of having attentional problems at age 7.

The developmental physiological mechanisms speculated to be responsible relate to the rapid development of the brain in young children. Environmental variables, including visual and auditory experiences, are thought to greatly influence the number and density of neuronal responses (Turner and Greenough, 1985; Greenough *et al.*, 1987; Wallace *et al.*, 1992). However, in contrast to the pace with which real life unfolds, television can portray rapidly changing scenes and events. Also, this speed of portrayal is not at all chronologically constant, but rather in itself varies greatly from moment to moment, scene to scene, show to show, movie to movie. Thus this unevenness and rapidity in depicting the passage of time, during the critical period of synaptic development in early childhood, is speculated to affect the number and density of neuronal responses (Christakis *et al.*, 2004). Although no similar research exists specifically for video games or movies, given their similarity one would be surprised if the same factors did not apply.

Internet and Socialization

One of the major trends in electronic media is the increase in use by children of younger ages. The National Center for Education Statistics (USDE, 2005) used a weighted sample representing approximately 58.3 million children aged 3 years and older in nursery school through the 12th grade in October 2003. A survey of this sample describes use of computer and Internet technologies by age group: 67% of children in nursery school were already computer users, as were 80% of those in kindergarten. About one-quarter (23%) of nursery school children were already Internet users, rising to about 32% in kindergarten. By high school, + nearly all students (97%) use computers and a large majority (80%) use the Internet (USDE, 2005).

The exponential rise in Internet use over a mere two decades from its initial availability offers little time to study its long-term developmental effects. However, these trends in adult Internet use at home clearly must have direct implications on time spent interacting with children, and indirect implications for parents as role models and gatekeepers of children's recreational choices. Nie and Hillygus (2002a) explore the effects of the Internet on interpersonal communication and sociability, collecting data from time diaries of their subjects. Internet use at home (but not at work) is shown to have a strong negative impact on time spent with friends and family as well as time spent on social activities. Similarly, Internet use during weekend days is more strongly related to decreased time spent with friends and family and on social activities than Internet use during weekdays. The relationship is highly significant: for every hour spent online at home or on the weekend, there is a corresponding 41 min less spent with family members ($\beta = -0.69$, $t\text{-stat} = -6.65$, $p < .001$). Nie and Hillygus (2002b) refined the parameters of this reallocation: in other words, what activities are affected, rather

than in whose company they are performed. Not surprisingly, Internet time seems to be reallocated most from discretionary activities, especially social activities, hobbies, reading for pleasure, and television viewing. However, Internet time is also reallocated from nondiscretionary activities such as housework and childcare, especially by heavy (≥ 61 min/day) Internet users. These findings seem to strongly corroborate the hypothesis that the Internet has created a shift in people's time allocation away from family and friends, and that this loss of time is suffered by a wide spectrum of specific activities.

Kraut *et al.* (1998) examine the social and psychological impacts of the introduction of the Internet to a household. The behaviors of 169 people in 73 households were tracked over the first 1–2 years of Internet use. Again, greater use of the Internet was associated with declines in communication with family members and in reduced social contact outside the home. In addition, increased Internet was associated with increases in loneliness and depression.

Media and Fear

Television and other electronic media probably provide most incidental information about nature (Bixler and Carlisle, 1994). As well as transmitting neutral information about nature, media depiction of nature's hazards can teach fear. Fears of evolutionarily relevant natural dangers such as snakes and spiders seem easier to acquire and harder to extinguish than fear of post-technological dangers such as cars and guns (Heerwagen and Orians, 2002). Children exposed to realistic media depictions of life-threatening events such as fire and drowning report feeling more at risk from those events and less likely to engage in activities related to the depicted tragedies (Bixler and Carlisle, 1994). Hence media depictions of nature tend to focus on and sensationalize nature's hazards, promoting the perception that natural areas are dangerous.

Similarly, for parents, sensationalism in the media has greatly reinforced paranoia over children being abducted while playing outdoors. Finkelhor *et al.* (1992) report 200–300 stereotypical criminal child kidnappings/year (approximately 0.00008% of the population) as opposed to the tens of thousands per year suspected in the public imagination. The best inoculation against inaccurate and sensationalized depictions of nature is an accurate frame of reference for nature built from early firsthand experiences (Bixler and Carlisle, 1994).

Children's firsthand experience in natural settings plays an important role in developing environmental attitudes and preferences for nature (Heerwagen and Orians, 2002). Without early and regular exposure to nature, urban dwellers find the unfamiliarity of wilderness settings uncomfortable and overwhelming (Bixler and Carlisle, 1994), preferring built settings to natural environments (Heerwagen and Orians, 2002).

Biophilia must be nurtured to truly take hold (Verbeek and de Waal, 2002). Active behaviors that require direct involvement with live animals, such as fishing, hunting, and bird-watching, lead to the most consistent environmental attitude and knowledge (Duda *et al.*, 2003). Values such as reverence and respect for nature appear to be derived in part from direct involvement (Matthews and Riley, 1995; Duda *et al.*, 2003).

Conservation and Virtual Nature

One of the most potentially controversial issues pertaining to videophilia is the issue of “virtual nature,” here defined as “nature experienced vicariously through electronic means.” What are the costs, what are the benefits? For there are indeed (at least in theory) benefits. Certainly, the Internet has provided unprecedented access to natural areas for many people. From a viewpoint solely focused on *Homo sapiens*, some of the relaxing and educational aspects of nature can in fact be delivered through vicarious experience (Levi and Kocher, 1999) on a video screen, or as technology advances, through a virtual reality space. An example is the National Park Service webcam showing Old Faithful in Yellowstone National Park (National Park Service, 2006). In particular, children, not able to travel to the Amazon rainforest or Old Faithful on their own, can do so online without the need for car, plane, or parent. Bugs, snakes, spiders, predators, and pests can all be left behind in virtual nature. There is even a little something for conservationists: endangered species and sensitive sites can be visited with little or no impact on habitat via webcam, and there is greatly reduced maintenance of natural areas when they do not have any real visitors. Lastly, whether or not we believe in the potential benefits of videophilia to conservation, we must unfortunately at least admit the possibility that the very strong current increase in videophilia (Pergams and Zaradic, 2006) is a juggernaut in whose way we cannot stand. This might leave virtual nature as the best related conservation option.

The potential costs of virtual nature to conservation are, of course, huge, and may be compounded in future generations. Environmental awareness, primarily nurtured through parents and adult mentors while outdoors (Chawla, 1998), may be the cost of replacing real nature with virtual nature, and this possibility should not be underestimated. Moreover, today’s children are tomorrow’s parents, but potentially with greatly decreased connection to nature. If children experience Old Faithful primarily through a webcam, where is the nurturing connection that in the past was provided by sharing the experience with family or an adult mentor? If parents and children are sharing the experience of virtual nature, will the nurturing connection be to the subject matter (nature) or to the media (the virtual experience)? From a conservation context, will they still go see it in real life? Will they still pay their tax in dollars to maintain Yellowstone?

Lacking direct experience of our natural environment, we lack the most immediate feedback of our impact on nature. Experiencing nature vicariously, we may not be aware of the sensory experiences we are missing through the virtual medium, but the real nature we leave outside will continue to receive the footprint of our presence on the planet. If we spend our recreational time on virtual tours, will we still pick up litter at our local parks? Or will we opt for solutions consistent with our simulated experience of nature? In Los Angeles, it was proposed to replace highway median plantings with plastic trees, rather than deal with the larger issue of air pollution (Levi and Kocher, 1999). In the long run, spending less time in real nature seems likely to speed the onset of environmental generational amnesia. This psychological phenomenon, described by Kahn (2002), is the tendency for each generation in its youth to take the existing environmental conditions as

normal, although with each ensuing generation the amount of environmental degradation increases.

If we generationally redefine normal conditions, we might well increasingly use experiences of vicarious nature as our benchmark rather than the local environment. A study of the effects of simulated experience through commercially available nature images suggests this type of vicarious contact with spectacular natural environments increases support for national parks and forests but decreases support for preservation and acquisition of local natural areas (Levi and Kocher, 1999). Thus vicarious nature experiences tend to sensationalize nature’s spectacular habitats, generating the perception that local natural areas are relatively lackluster.

Given that the frequency of direct contact with nature depends on local availability (particularly for children, due to their dependence on caregivers for access; Louv, 2006), the devaluing of local natural areas as compared with sensationalized virtual views of nature seems likely to further reduce direct experiences, and perforce increase our reliance on vicarious nature experiences. Moreover, the recent decline in *per capita* NPV (Pergams *et al.*, 2004; Pergams and Zaradic, 2006) suggests that although vicarious exposure to spectacular habitats may increase the perceived value of national parks, this increased value does not translate to increased direct experiences. In fact, the results of the authors’ research suggest just the opposite, that increased use of virtual electronic media is significantly correlated with decreased direct experiences with national parks (Pergams and Zaradic, 2006). Concurrent with the almost 25% decline in NPV, Internet use increased from none in 1987 to a per person annual average of 174 h by 2003, and average overall annual electronic media use (home movies, theatre movies, video games, and Internet use) rose by an average of 327 h per person (Pergams and Zaradic, 2006). Thus virtual access to nature is, in our data, already very strongly associated with loss of direct contact with actual nature. In other words, visiting Old Faithful on the web more seems to result in visiting Old Faithful in person less.

Videophilia Implications for the Future

Videophilia has both direct and indirect implications for childhood development and the future of conservation. We may well be seeing evidence of a fundamental shift away from biophilia, “the innate tendency to focus on life and lifelike processes” (Wilson, 1984, elaborated with Kellert and Wilson, 1993, and by Kahn, 1997) to videophilia. Moreover, adult attitudes toward the environment are often nurtured through family vacations and spending time outdoors with family and mentors (Chawla, 1998). If parents, mentors, and children are indeed spending less recreational time in nature (Louv, 2006), the implications for conservation and impacts on childhood development may be compounded in future generations.

Most directly, increasing videophilia has been implicated in negative psychological and physical effects. Some of the negative effects are linked to the sedentary nature of videophilia and reduced time available for outdoor physical activities and nature experiences. Conversely, outdoor play and nature experience have proven beneficial for cognitive functioning, reduction in symptoms of ADD, increase in self-discipline, and emotional well-being at all developmental

stages. Other detrimental effects of videophilia seem to be more related to its potential for isolation and much faster pace than real time. High levels of children's electronic media consumption is correlated with attentional problems and increases in loneliness and depression.

Potentially more complex are the implications of virtual nature. Virtual nature, here defined as "nature experienced vicariously through electronic means," has some potential benefits, particularly for children who are dependent on adults for access to many natural areas. Although a sedentary videophilic outlet, the Internet provides unprecedented access for children to natural areas, delivering some of the relaxing and educational aspects of nature vicariously. Yet, given increasing Internet usage by younger children, virtual nature appears to directly compete with time previously allocated to the more beneficial direct contact with the outdoors. In addition, virtual nature experiences may further discourage direct contact with local nature by sensationalizing nature's hazards and habitats, generating the perception that local natural areas are simultaneously both dangerous and lackluster.

Ultimately, to more conclusively resolve the long-term impact of videophilia, further research is needed to answer the questions of exactly what videophilia means to (1) children's development, (2) their success and happiness as adults, and (3) specifically, their environmental consciousness. The authors propose the initiation of a large-scale longitudinal study to determine the effects of videophilia on children's development and future outcomes. Such research would follow controlled groups of children from birth to adulthood, and quantify differences in as many areas as possible, correlated to exposure to nature and/or videophilia. Physical and mental health, educational achievement, career choices, and economic success as adults would all be among areas considered in addition to environmental awareness. The proposed research would require the cooperation of a number of experts from a wide variety of fields. As daunting as the proposal might seem, children are already exposed, at earlier and earlier developmental stages, to an uncontrolled videophilia treatment. More daunting is the prospect of today's children (tomorrow's parents) in a culture devoid of contact with the evolutionary driver and life-support system that is our natural world.

Conservation's Current Base of Support

A Narrow Base

Coincident with the decline in popularity of nature-based recreation, a review of recent trends suggests that current public support for conservation has a narrow base, and that existing support is not strong enough to make conservation or the environment a high priority (Earthjustice, 2005; Nordhaus and Shellenberger, 2007). A 2004 survey of the electorate determined that Americans are increasingly indifferent to environmental issues, with the environment ranking lower than most other voter priorities (Shellenberger and Nordhaus, 2004; Earthjustice, 2005; Nordhaus and Shellenberger, 2007). Finally, populations globally and within the USA are increasingly urban, meaning there simply is less contact with nature in any form (UNPD, 2005; Kareiva, 2008). All of these trends

combine to suggest that one of the greatest threats to conservation may be declining public support due to a progressively smaller population engaged in outdoor recreation and as a result less willing to support conservation activities.

Not All Nature Recreation Is Equal

Not all types of nature recreation are equal when it comes to generating conservation support. Some types of nature recreation are more likely to generate a strong constituency of conservation supporters. In addition to the impact of broader economic forces on support for conservation (Pergams *et al.*, 2004; Butler, 2009), participation in specific types of nature recreation may be more indicative of conservation support, potentially with some time delay between the participation and the support. Zaradic *et al.*, (2009) used annual contributions to four large conservation nongovernmental organizations (NGOs: The Nature Conservancy, World Wildlife Fund, Sierra Club, and Environmental Defense Fund) as a longitudinal measure of conservation support. The nature exposure time series were updated from those utilized in Pergams and Zaradic (2008). Conservation contributions reflect the relative priorities of the donors, as well as the state of the US national economy and changes in both corporate and personal income and wealth (Pergams *et al.*, 2004). As appropriate, values were weighted *per capita* and/or inflation-adjusted to 2001 dollars using the appropriate time series of gross domestic product (GDP) deflators from the US Federal Reserve.

Contributions to the major conservation, NGOs were positively correlated with *per capita* backpacking and hiking 11–12 years earlier, but negatively correlated with less elite outdoor activities, such as public lands visitation or fishing. A chart comparing *per capita* annual conservation NGO contributions with *per capita* backpacking and hiking time series is given in Figure 1. The backpacking and hiking series are shown lagged in time to match the significantly correlated year of investment. Backpacking/hiking time series show longer-term increases, but with peaks in 1998–2000 and declines since then.

The declines in backpacking/hiking since 2000 could imply a significant problem for conservation support. Backpacking is defined in the survey data as 1+ overnight trips, including wilderness camping, so backpackers require time and gear, both of which are relatively expensive. The two sets of survey data for backpacking, and the most extreme version of backpacking (complete thru-hiking of the 2000+ mile Appalachian Trail) are measures of similar, exclusive, high-cost and time-intensive nature recreation. Backpacking tends to be more attractive to younger age groups. Most backpackers are in the 25–44 age range and overwhelmingly European American (NPS, 2001; Cordell *et al.*, 2005). Using the most parsimonious interpretation of the time lags, these primarily European American former backpackers become a significant source of NGO dollars 11–12 years after backpacking.

The Two Americas of Conservation Support

The type and timing of nature exposure makes a great deal of difference when it comes to creating later conservation support.

The interpretation of Zaradic *et al.*, 2009 is that there are effectively two Americas when considering the pathway from nature exposure to conservation support: an elite backpacking/hiking group and a broader public lands visitation group. If this is true, then it has profound consequences for future generations and prospects for conservation support. Conservation organizations seem to be receiving donations from a very narrow group of relatively elite outdoor enthusiasts. The three variables that were highly positively correlated with conservation NGO contributions are all variations of backpacking. Backpacking represents the least popular of the four classes of recreation variables studied (Pergams and Zaradic, 2008). The current *per capita* rate of backpacking is 0.054; in other words, the average American goes backpacking once every 18.5 years (Pergams and Zaradic, 2008). Each hiker or backpacker translates to \$200–\$300 annually in future NGO contributions. Given that most backpackers are 25–44 and adding the 11–12 year time lag, this would most likely be in middle age, presumably near their income prime. The demographics of this group are consistent with the description of the small fraction of the electorate that considers the environment a top priority: overwhelmingly European American, mostly college educated, higher income, and older than 35 (Earthjustice, 2005). Furthermore, based on the lagged impact of hiking/backpacking on investment, conservation NGOs have been benefiting from the tail end of a decade-old rise in the popularity of backpacking and hiking (Figure 1). The most recent data show a decline in hiking/backpacking popularity since 1998–2000 (Pergams and Zaradic, 2008). The authors project the negative effect of reduced hiking/backpacking frequency on NGO revenues to begin in approximately 2010–2011, and to continue through at least 2018 (Figure 1).

In contrast to backpacking, nature recreation at public lands appears much less likely to translate to conservation NGO investment. Moreover, there is apparently relatively little backpacking and hiking occurring during public lands visitation. For example, a recent survey of 849 Yellowstone NPV groups asked what primary activities were their reasons for visiting the park (Manni *et al.*, 2007, Figure 43). Seven activities accounted for 92% of reasons: sightseeing/taking a scenic drive (59%), viewing wildlife/birdwatching (16%), boardwalk/geyser basin (9%), camping in developed campgrounds (3%), day hiking (3%), viewing roadside/trailside exhibits (1%), and overnight backpacking (backcountry) (1%). All other activities were <1% of reasons. With backpacking and hiking combined being only 4% of the reasons, people gave for visiting Yellowstone, there is probably little ambiguity between public lands visitation data and data acquired specifically about backpackers and hikers.

In addition, there appears to be a large income gap of (very roughly) 30–70% between backpacker/hikers and public lands visitors. Based on a 30-year review of outdoor recreation literature by the US Department of Agriculture (Loomis, 2005), average income (in 1996 inflation-adjusted dollars) of backpacker/hikers is \$70,222. In contrast, the median household income for SPV and NPV (in 1996 inflation-adjusted dollars) is \$42,100–\$44,438 (South Carolina DPRT, 2001). The average income of sport fishermen of \$43,410 is comparable with that of park visitors. Similar income gaps can be detected using market surveys of specialty magazines: *Field and Stream* for

fishing/hunting (2008 annual circulation 16,500,000) has an average reader income of \$54,838 (Echo Media, 2009a), whereas *Backpacker* magazine for hiking/backpacking (circulation 2,790,000) has an average reader income of \$70,950 (Echo Media, 2009b).

Increased exposure to nature through public land visits (SPV, NPV, NFV, and BLMV) is significantly negatively correlated with conservation NGO contributions. Fishing is strongly associated with public lands; typically 80–85% of all fishing takes place on public water bodies (State of Virginia, 2007). People who get their primary nature exposure from visiting public lands or fishing are much more diverse in age and ethnic composition (NPS, 2001; Cordell *et al.*, 2005). For example, in the African American community, fishing is more than seven times as popular (in *per capita* participation) as backpacking and more than twice as popular among the Hispanic community (Cordell *et al.*, 2005). Similarly, NPV is approximately three times more popular among Hispanics and four times more popular among the African American community as compared with backpacking (NPS, 2001). The negative correlation between public land visitation and NGO contributions appears to hold both for short-term conservation investment (4–7 years after the nature experience) and for the longest-term measures we could obtain (approx. 16 years later). The authors hypothesize that people are more likely to invest in what they know from firsthand experience. Indeed, it may be that high levels of public land recreation might create a sense that access to the outdoors is what is important rather than preserving less accessible landscapes through conservation NGOs. Whatever the reason, it is important to acknowledge that all nature participation is not equal in terms of generating support for conservation, and that to the extent that conservation needs to broaden its support base, there is a need to understand what type of nature recreation creates the strongest commitment to conservation.

Need to Diversify

Given the trends of increasing US population diversity, urbanization, and economic and cultural changes, the authors fear that the currently narrow base of conservation NGO supporters will become even narrower. To avoid becoming marginalized, the conservation movement will need to diversify its outreach strategy, engaging novel and diverse constituencies. Strategies for doing so may require either more of the “right types” of nature exposure or entirely different approaches to ethnic or socioeconomic groups who are not likely to engage in hiking and backpacking. Ultimately, the fate of biodiversity and intact ecosystems may depend less on rates of habitat loss or invasive species than on public perception of whether conservation should be supported at all.

Demographics and Conservation's Future Base

Current conservation support depends primarily on a very narrow group of relatively elite outdoor enthusiasts: overwhelmingly European American, mostly college educated, higher income, older than 35, former backpackers and hikers 11–12 years after their peak of outdoor participation (Zaradic *et al.*, 2009). Given the trends of increasing US population diversity, urbanization,

and economic and cultural changes, this narrow base of conservation supporters is likely to become even narrower (Zaradic *et al.*, 2009). By 2042, the non-white population in the USA is predicted to become the majority of the population. Today's young people are leading this demographic shift, that is, 40% of US youth aged 25 and younger are non-white, 44% of youth aged 18 and younger are non-white, and 50% of children aged 5 and younger are non-white (US Census, 2010). Nationally and globally, the field of conservation will depend on the support of this coming generation.

Speaking to and attracting a younger and more diverse urban constituency requires targeted outreach. Programs such as the The Nature Conservancy's Leaders in Environmental Action for the Future (LEAF) program target young people characteristic of the growing demographic shift in diversity, and at a young adult age during which outdoor participation tends to decline sharply (Outdoor Foundation, 2010). The primarily (85%) non-white LEAF participants and alumni represent the types of diverse future leaders and environmentalists that will be needed to support global conservation goals. Spending sustained time in nature, particularly with a mentor, is thought to be one of the foundations for nurturing the types of environmental attitudes and values leading to long-term conservation support (Bögeholz, 2006; Lang, 2006; Wells and Lekies, 2006; Zaradic and Pergams, 2007). The LEAF partnership model is based on providing a sustained nature experience, facilitated by mentors. By combining what students are learning in environmental high schools with real-world nature stewardship experience in the field with a mentor, The Nature Conservancy's LEAF seems to create an ideal environmental foundation (Bailey *et al.*, 2004; Rickinson *et al.*, 2004) for its participants. LEAF alumni are outdoor enthusiasts, environmental advocates, and volunteers, and they influence their peers and community (Zaradic and Pergams, 2011).

Conservation Based on Purely Selfish Motives

Ecosystem Services

Against a background of increased videophilia and concurrent decreased nature participation, we have seen a new field of applied research come into being. The new field of ecosystem services attempts to economically value the biodiversity that directly serves human needs. To value nature's systems completely and coherently in our chaotic world is, of course, impossible. We try anyway, for the sake of the many people who place little or no intrinsic value on nature. Some of these people are from developed countries, and may have already become distanced from nature though videophilia. Others are from less-developed countries and may be forced to prioritize immediate human needs (like food and shelter) over conservation.

In any case, ecosystem services valuations exist so that conservationists are allowed at the table where ministers of commerce, transportation, defense, etc. sit, in an attempt to alter their behavior and policies. Until conservation is translated into monetary value, it is viewed by most people as a curiosity. As a result, conservationists need to remind

everyone that looking only at immediate commercial payoffs (say, from fisheries) will consistently undervalue biodiversity, given the enormously broader range of tangible and intangible services fisheries provide. The challenge is to deduce the value that people do or should place on species (should, because species are often providing indirect benefits not immediately appreciated by observers), including the intangible aspects of that value. The value of biodiversity to human health consists of such undervalued and little-discussed benefits.

Health Benefits

In developed nations, local ecosystems are degraded with the assumption that health care and alternate access to provisions ameliorates any health impact. Many developed nations enjoy a fair amount of *per capita* investment in health care (United Nations, 2007, 2009), and the average lifespan, prenatal care, and few disability days in those countries reflects a high level of health. As a result, in developed nations, mortality is increasingly related to environmental issues and a sedentary lifestyle (WHO, 1997, p. 132, 2000), including diseases such as coronary disease, cancer, and diabetes (WHO, 2008).

There may be some nonsubstitutable health benefits of active exposure to intact ecosystems. Parks and other local green spaces, Internet/webcam access to wild nature, and outdoor recreation campaigns may be attempts at creating a substitute for the benefits of access to intact ecosystems. The marginal health value and the degree of substitutability of these nature access alternatives remain unquantified unknowns. However, the increasing mortality related to sedentary lifestyle and stress-related disorders suggest that the quantity and quality of current substitutes is inadequate. If regular access to intact ecosystems can be shown to address the medical ills of modern developed life, then this supports a market for conserving local intact ecosystems and also, through ecotourism, for intact ecosystems throughout the globe.

There appear to be links between videophilia and decreasing participation in nature-based recreation. There is a further body of work that suggests active exposure to nature reduces stress and provides other aspects of physical and psychological well-being. It is possible that access to intact ecosystems may provide the greatest added health benefit in those very developed areas where intact ecosystems are most rare. Although the added health benefit in years of longevity may be relatively small, it is of the greatest marginal benefit to the wealthiest sector of the global population: those on the most developed, highest-GDP parts of the world. It may be that those areas that have access to the best modern medical care in fact have the most marginal health benefits to gain from access to intact nature. If videophilia and its accompanying ailments are the side effects of living in an urban, developed environment, and regular access to nature is the cure, then the same market forces that drive exploitation can be harnessed to drive conservation.

Proposed Research

In closing, the authors would like to suggest research uniting most of the themes in this article. They propose construction

of a complex, multivariate model with the capacity to predict conservation effort in the USA with a high degree of accuracy. Such a model would elucidate the underlying economic factors and nature experiences that sustain conservation, and show how these factors relate to specific aspects of natural systems. This model would be of enormous use to conservation entities of all sorts, from governmental agencies to large NGOs to grassroots organizations. It would also further our understanding of the social and economic motivators driving the US conservation movement.

In addition to evaluating national-scale longitudinal trends, the authors suggest identifying smaller populations with comparable nature exposure, as well as corresponding control groups. Here their goal is twofold: (1) they wish to determine the extent to which their models can be utilized on smaller, regional scales and (2) they would like to characterize as precisely as possible the age, setting, and type of nature exposure that leads to the highest value being placed on natural areas and conservation. These latter results would be extraordinarily useful for environmental educators, and are particularly cogent in light of the No Child Left Inside Act (H.R. 3036 and S. 1981; see also Pergams, 2008).

Over the last 7 years, the authors have developed a line of research on the relationships among natural systems, biodiversity conservation, and economic forces. Pergams *et al.* (2004) predicted revenues to major conservation NGOs and acreage of new federal protected lands based on corporate and individual incomes with a high degree of accuracy ($p < .0005$) and predicted the drop in conservation investment during the current economic crisis. Of further interest, one of the variables gathered (*per capita* NPV in the USA) was shown to be in decline since 1987, after a previous 50 years of steady increase.

Pergams and Zaradic (2006) tested possible proximate causes of this drop in nature recreation and found that a model consisting of four entertainment media usage variables (hours of video games, home movies, theatre attendance, and Internet use) as well as oil prices explained the decline (adjusted multiple $r^2 = 0.925$, $p < .0001$). The authors coined the word “videophilia” to describe this phenomenon.

The breadth of decline in nature exposure was revealed in Pergams and Zaradic (2008). Beyond US national parks, the authors examined 16 time series in nature visitation across state and federal public lands (both in the USA and abroad)

Figure 4 Comparing annual *per capita* contributions to conservation NGOs and participation in backpacking and hiking. Gaps in the backpacking time series are due to lack of data for those years. “NGO contributions” is aligned with actual year of contribution on the x-axis. The backpacking and hiking series are shown lagged by +11 or +12 years to match the significantly correlated year of NGO revenue. In other words, data for “NGO Contributions” for 2006 are depicted on the graph at x-axis year 2006 along with the correlated data for “Backpack Hike” from 1995, “AT hiking” from 1995, and “Backpacking” from 1994. Based on the correlation between these variables, a decline in NGO contributions would be projected until at least 2018.

as well as other nature-related recreation activities. Typical declines in nature recreation began between 1981 and 1991 and proceeded at rates of -1.0% to -1.3% per year, with a total to date of -18% to -25% . The drop in nature recreation is indeed generalized in the USA (and potentially in other developed nations such as Japan) and has been characterized as possibly the world's greatest environmental threat (Kareiva, 2008).

Zaradic *et al.*, 2009 suggests that the type and timing of nature experience may determine future conservation investment. Time spent hiking or backpacking is correlated with increased conservation contributions 11–12 years later. However, contributions are negatively correlated with past time spent on activities such as public lands visitation or fishing (Figure 4).

The authors' published findings are represented as solid arrows in the conceptual map below (Figure 5). The dotted arrows represent proposed research. The map itself depicts the relationships the authors perceive between independent variables (ovals) of (1) nature exposure, (2) electronic media usage, and (3) economic forces; and dependent variables (rectangles) of (1) biodiversity conservation effort and (2) quality of natural systems. The authors propose research to evaluate the following questions:

1. Nature Exposure $\rightarrow$ Biodiversity Conservation. Does nature exposure influence future environmental consciousness? Research in the social sciences (and common sense) suggests

that nature values are highly influenced by direct contact with nature (Hungerford and Volk, 1990; Wells and Lekies, 2006), particularly in childhood (Duda *et al.*, 1998; Zaradic and Pergams, 2007) and with a role model (Matthews and Riley, 1995; Chawla, 1998). Zaradic *et al.*, 2009 evaluated whether various forms of nature recreation and exposure to nature are significantly associated with later conservation effort and quantify the degree of these relationships and the time lags between them. Experimental work could further validate and explore the relationship between timing and duration of specific types of nature recreation and later conservation ethics.

2. Natural Systems $\rightarrow$ Nature Exposure. There is a feedback loop between the quality and accessibility of natural systems and the amount of time people are willing to spend in these systems. The authors propose quantifying these relationships and the time lags involved.
3. Economic Forces $\rightarrow$ Natural Systems. A growing economy has positive effects on conservation effort (Pergams *et al.*, 2004). However, a growing economy is associated with increased consumption of natural resources; habitat degradation, loss, and fragmentation; pollution; climate change; etc. The authors propose the characterization of how such individual aspects of our natural systems are affected by individual economic forces.
4. Biodiversity Conservation $\rightarrow$ Natural Systems. Increased conservation effort no doubt results in improved aspects of natural systems. But which aspects of biodiversity

Figure 5 A conceptual map of current and suggested research on the connections between nature exposure, videophilia, and economics and their impact on conservation and the quality of natural systems. The map depicts the relationship between independent variables (ovals) of (1) nature exposure, (2) electronic media usage, and (3) economic forces; and dependent variables (rectangles) of (1) biodiversity conservation effort and (2) quality of natural systems. The authors' published findings are represented as solid arrows in the conceptual map. The dotted arrows represent proposed research.

conservation result are most efficient? How long does it take, on average, for these improvements to have effect?

5. Videophilia → Biodiversity Conservation. The authors have shown the likelihood of a time swap between use of electronic media and nature exposure (Pergams and Zaradic, 2006). They would like to evaluate whether there is also a direct time swap between use of electronic media and effort put into conservation, what types of conservation effort are affected, and what the time lags are.

Aesthetic Factors

Gordon H Orians, University of Washington, Seattle, WA, USA

© 2013 Elsevier Inc. All rights reserved.

Glossary

Aesthetics The field of investigation, from philosophical and psychological perspectives, that attempts to discover the rules and principles that govern the sense of beauty and ugliness.

Beauty The qualities of a perceived or imagined object whereby it evokes feelings of admiring pleasure.

Cognition Act or process of knowing and understanding.

Habitat Type of environment in which an organism lives, grows, and reproduces.

Phobia Obsessive fear or dread of an object or situation.

Symmetry The correspondence in size, form, and arrangement of parts on opposite sides of a two- or three-dimensional object.

Aesthetic factors are those characteristics of a given object or situation that evoke a certain emotional response, either a sense of beauty, attractiveness, pleasure, symmetry, order, and so on, or, conversely, of ugliness, disorder, menace, disgust, or the like. Generally speaking, the aesthetic preferences that humans display in response to their environment, in such contexts as mate choice, foraging, and habitat selection, have been shaped by evolutionary experience and embody solutions for survival and reproductive success.

Introduction

Humans have strong emotional responses to living organisms and to natural and human-modified environments. Depending on the circumstances and needs of an individual, nature may evoke feelings of awe, respect, fear, loathing, longing, nostalgia, excitement, challenge, and belonging. These powerful emotions influence how we respond to nature, how we attempt to manipulate it, and why we care about it.

Strong emotional responses in all organisms, including humans, evolved because, on average, they increased fitness, that is, they improved the survival and reproductive success of the individuals that expressed them. For example, those of our ancestors who did not enjoy food and sex certainly were more poorly represented in subsequent generations than those who did enjoy and hence sought out food and sexual partners. Similarly, individuals who chose ecologically inferior environments in which to live should have been less well represented genetically in subsequent generations than individuals who made better habitat choices.

However, this truism does little more than establish general guidelines for investigating why human emotional responses to components of the environment are so varied. Nor does it take us very far in improving our understanding of how different emotional responses to varied environmental components resulted in fitness-improving behaviors. Specific theories and analyses are needed.

Evolutionary Approaches to Environmental Aesthetics

Why human emotional responses to nature would have influenced fitness is obvious. Our ancestors lived in environments

devoid of modern conveniences. Their health, survival, and reproductive success depended on their ability to obtain and use environmental information wisely. They had to know how to interpret signals from the physical and biological components of the environment, and to adjust their behavior in response to them. They needed to evaluate habitats and their resources over space and time, and to adjust their use of habitats accordingly. Our ancestors also needed to be able to detect the presence of other humans, their effects on resources, and the direct dangers they posed or the help they might provide.

Making these evaluations and decisions was and still is difficult because the environment provides a far richer array of information than can possibly be assimilated and synthesized. Adaptive behavior requires selective attention to components of the environment that strongly influence fitness. In fact, the complex behavior of organisms would be impossible in the absence of neural filters that emphasize or deemphasize aspects of information emanating from the environment. These filters embody evolutionarily stored knowledge about the world that enables us to construct hypotheses capable of describing and understanding the external world. Extensive experiments on artificial intelligence have clearly shown that the rapid and efficient learning of a language performed by nearly every human child is quite impossible in the absence of pre-formed neural structures (Dennett, 1995).

These filters express themselves in all organisms as a sense of aesthetics and some form of logical analysis. In other words, aesthetic responses, rather than being a recently acquired capacity of little evolutionary significance, are fundamental to the ways in which organisms learn about the world and adapt to it. The English word *aesthetic* is derived from the adjectival form of the Greek *aisthanomai*, which means "to perceive." Thus, "aesthetic pleasure" means literally "pleasure associated with or deriving from perception." The central problem in aesthetics is to explain why pleasure and disgust have evolved to be so strongly associated with perception and recognition of certain kinds of objects.

The evolution of neural filters has led to what is called *biologically prepared learning* (Seligman, 1970). Biologically prepared learning theory asserts that evolution has predisposed humans, as well as individuals of other species, to learn easily and quickly, and to retain associations or responses that foster survival when certain objects or situations

are encountered. An important corollary is that even though modern societies have greatly reduced the real danger posed by many objects that evoke fears and phobias, fear and avoidance responses may nonetheless persist because selection against those responses is weak (Ulrich, 1993; Wilson, 1984). Biologically prepared learning in humans should be evident only for stimuli that have had significant influences on survival and reproductive success during our evolutionary history. Those responses should arise quickly when the appropriate conditioning stimuli appear, and they should be unusually resistant to extinction or forgetting. Adaptive responses to natural stimuli do not necessarily appear spontaneously or in the absence of learning, but they may.

Although aesthetic inquiries have been carried out since the middle of the eighteenth century, attention has been directed almost exclusively to responses to human creations rather than to nature. The neglect of nature is a by-product of the view that has dominated Western thinking for centuries – namely, that aesthetic experiences are molded primarily by cultural symbols and art forms. As a result, the study of aesthetics has been viewed as the domain of artists and philosophers. Attempts to explore the biophysical bases of aesthetic responses to environments were regarded, and still are by some people, as both futile and ideologically dangerous.

Culture and learning clearly exert strong influences on the ways humans perceive and respond to environmental information and they have important impacts on the symbolisms we attach to natural objects (Appleton, 1990; Dutton, 2009; Schama, 1995). But attempts to understand and interpret human aesthetic responses to environmental features without asking why they evolved have failed. People who studied the concept of beauty from a nonbiological perspective assumed that beauty was an intrinsic property of objects. They therefore looked for, and expected to find, correlations between the characteristics of objects and human aesthetic responses to them. This attempt largely failed because, as an evolutionary perspective immediately suggests, beauty is not an intrinsic property of the objects that we call beautiful. Rather, it is the product of interactions between traits of objects and the human nervous system that evolved so that we regard as beautiful those objects having properties that, if positively attended to, result in improved performance in some aspect of living (Appleton, 1975). Conversely, we regard as ugly those objects that should be avoided or destroyed. In essence, an evolutionary perspective suggests that concepts such as beauty and ugliness should be viewed from a functional rather than a structural perspective. In other words, emotional responses are

best studied by asking “How did these responses help us solve problems?”

Environmental Information, Problem Solving, and Survival

Individuals of all species use information to make decisions that enhance their survival and reproduction. The array of information presented to an individual has components that are highly relevant to survival and reproductive success, and components that can be ignored with few or no adverse consequences. In addition, which components are important varies with time, location, and the needs of the individual.

Progress in the study of environmental aesthetics and problem solving has been aided by the development of systems for classifying environmental information into categories that roughly correspond to the kinds of decisions that organisms must make (Heerwagen and Orians, 1993). The basic problems that people (and other animals) must solve are: (1) protecting themselves from being injured or killed by other people or dangerous animals; (2) avoiding being attacked by parasites and disease-causing organisms that may be acquired from people or from other sources; (3) protecting themselves from adverse physical conditions; (4) acquiring enough of the right kinds of food; and (5) choosing good-quality associates for reproduction, foraging, protection, and achieving higher social status.

One useful classification divides information into categories based on the type of objects being identified. Some of these objects, such as food, water, and refuges, are resources. Gathering information about these resources should be pleasurable and exciting. Other objects, such as potentially dangerous animals, competitors, human enemies, and hazardous physical objects, pose dangers. Some of them are life-threatening, but others, although potentially dangerous, can be overcome. Gathering information about them should be accompanied by feelings of fear, anxiety, and apprehension rather than pleasure (Table 1).

Another classification of environmental information is based on the time frame over which the information is relevant. Although time is a continuous variable, humans long ago discovered that it is heuristically useful to divide time into categories. From the perspective of the study of environmental aesthetics, it is informative to divide time into categories that correspond to the time frames over which decisions about them matter (Table 2). Some environmental information

Table 1 Classification of information by type of object

<i>Category</i>	<i>Examples</i>	<i>Decision affected</i>
Inanimate objects		
Stationary	Landforms, glaciers	Bases of operations
Mobile	Rivers, ocean surface	Timings of foraging and exploratory activities
Animated objects		
Resources	Food items, fiber, medicine sources	Types, locations, and timing of foraging trips
Dangerous	Predators, large prey, venomous plants and animals, disease-causing, or disease-vectoring animals	Types, locations, and timing of foraging trips

Table 2 Classification of information in terms of the time frame of its relevance

Category	Examples	Decision affected
Short term (minutes to hours)	Weather changes (thunderclouds, wind) Appearance of dangerous animals, enemies Appearance of valuable prey illumination changes	Seeking shelter, initiating outdoor activities Immediate defensive actions Immediate hunting activities moves to appropriate locations for spending the night
Seasonal	Day-length changes, vegetative growth, flowering, precipitation changes	Shifts of hunting sites, planting and harvesting of crops
Multiyear changes	Vegetation succession, erosional changes (river meanders, lake sedimentation)	Shifts of hunting sites, movement of villages
Long term (decades to centuries)	Topography	Development of tradition

Source: Reproduced from Orians GH (1998) Human behavioral ecology: 140 years without Darwin is too long. *Bulletin of the Ecological Society of America* 79: 15–28.

signals events of immediate, temporary significance. Still other information signals seasonal changes that are associated with shifts in the types and locations of resources that will be available in the near future. Still other information signals features of the environment, such as status of vegetation and courses of rivers, that change slowly over periods of years or decades. Finally, other information arrives from objects that, measured in terms of human lifetimes, are permanent.

A third classification is based on the sensory mode in which the information arrives. What information can be perceived obviously depends on the sensory capacity of an organism and its neural processing system. The first, and still the most important sensory capacity in the living world as a whole, is chemical sensitivity. Molecules arrive by diffusion, augmented by movements of the medium. All chemicals are sensed when they come into contact with an organism's body, but, based on how fast they are carried by air currents, we distinguish verbally between the senses of taste and smell. The chemical knowledge possessed by a single bacterial cell exceeds what the most sophisticated organic chemist can measure. And because the sense of taste is based on chemical reactions, noses can be scaled down almost to the size of molecules.

Light sensitivity also evolved early in life's history on Earth. Bacteria evolved both photosensitivity – light-sensitive spots – and photosynthesis. The former vastly increased the distance over which objects could be detected; the latter generated nearly all the energy in today's biosphere. Because light travels in straight lines, at the speed of light, vision potentially provides accurate and time-specific information about shapes of objects and their location in space. Sound has similar properties to light, but location of objects is not given precisely. Animals have evolved complex ways of inferring locations of sources of sounds by comparing events at the two ears.

Nervous systems evolved in part because, by building up parallel computing units, they enabled organisms to speed up and amplify responses to sensory inputs. For motile organisms, speed of response is often extremely important. Parallel computing units also are the units in which neural filters are stored.

Responses to environmental information are complex because the significance of objects and events varies with the location and needs of observers. An approaching storm may be welcomed by a farmer whose crops are wilting from lack of

rain, but despised by members of a family enjoying their first summer picnic. A vivid sunset enjoyed by people relaxing on the deck of their home may bring fear to a person walking on an African savanna too far from home to reach it before dangerous nocturnal predators become active. For these reasons, simple correlations between features of objects and aesthetic evaluations are unlikely ever to be discovered, although correlations between types of objects, contents, and aesthetic responses are likely.

Three functional concepts – prospect, refuge, and hazard – have guided recent approaches to the role of environmental aesthetics in problem solving (Appleton, 1975). *Prospect* refers to the ability of an individual to gather information about an environment with which to evaluate its characteristics and decide how to use it. Environments high in prospect offer rich opportunities for evaluation; environments low in prospect offer fewer opportunities. *Refuge* refers to the degree to which an environment provides security for an individual from negative agents while it is exploring and gathering information. *Hazard* refers to the dangers to which an individual would be exposed during information-gathering activities.

These concepts have been applied primarily to the initial evaluation and exploration of unfamiliar environments, but when combined with more recent developments in evaluating environmental information, they are readily applied and extended to a rich array of circumstances in which people must solve problems.

Emotional responses that assist in solving these problems necessarily include both positive and negative components. Because they are simpler and easier to study, the author discusses negative responses first.

Negative Emotional Responses

Many people have strong fearful reactions – phobias – to a wide variety of objects or situations (snakes, spiders, heights, closed spaces, open spaces, blood). The set of objects that evoke fearful responses appears to be the same in all industrialized societies for which data are available (Ulrich, 1993), but few data exist on the prevalence of phobias in developing nations and nontechnological societies.

The objects and situations that evoke fearful responses are generally ones that have been associated with threatening

situations during human evolutionary history. Precipitous cliffs are dangerous if approached too closely. Closed spaces offer few escape routes; people in wide open spaces are vulnerable to attacks by enemies and dangerous predators. Venomous and predatory animals have been significant sources of human injury and mortality for many millennia (Isbell, 2009). Interestingly, even though they account for trivial numbers of injuries and deaths in modern societies, spiders and snakes are the objects of the most prevalent phobias in Western societies today.

Research on human twins has provided convincing evidence that genetic factors play major roles in a wide range of human traits, including animal phobias and fear of open spaces. Imaginative research, especially by psychologists in Sweden and Norway, shows that biologically prepared learning plays a significant role in the acquisition and retention of phobias (see Ulrich, 1993, for an overview of experimental results). The most informative experiments employ a Pavlovian conditioning approach to compare the development of defensive and aversive conditioned responses (learned through repeated exposure or experience) to slides of fear-relevant and fear-irrelevant or neutral stimuli. Defensive responses are assessed by recording autonomic nervous system indicators such as skin conductance and heart rate.

Experimenters condition initial defensive responses by showing either fear-relevant (snakes or spiders) or neutral stimuli (geometric figures) paired with an aversive stimulus (the unconditioned stimulus), usually an electric shock intended to mimic a bite. This phase allows experimenters to compare the speed and strength of acquisition of defensive/aversive responses to fear-relevant and neutral stimuli.

Following an initial acquisition phase, the same stimuli are presented many times without electric shock reinforcement. This “extinction” phase allows comparison of the rate of extinction of the defensive/aversive response acquired earlier. The general result is that conditioned responses are usually, but not always, acquired more quickly, but that responses to snakes and spiders are reliably more resistant to extinction than responses to neutral stimuli. These responses cannot be the result of prior cultural reinforcement, because conditioned aversive responses to familiar modern dangerous stimuli, such as hand guns and frayed electrical wires, extinguish more rapidly than conditioned responses to snakes and spiders. In addition, aversive responses to fear-relevant natural stimuli can be elicited merely by telling a person that a shock will be administered. Aversive responses to fear-irrelevant natural stimuli cannot be elicited in this manner.

People also acquire much more persistent defensive reactions when watching an experimenter’s reactions to fear-relevant than to fear-irrelevant stimuli. Similar results have been obtained by exposing rhesus monkeys to fear-relevant (toy snakes and crocodiles) and fear-irrelevant stimuli (toy rabbits).

Even more striking are the results of “backward masking” experiments, in which slides are displayed subliminally (for 15–30 ms) before being “masked” by a slide of another stimulus or setting. Even though the subjects are not consciously aware of having seen the stimulus slide, presentations of natural settings that contain snakes or spiders elicit strong aversive/defensive reactions in nonphobic persons. If a

previous conditioning has already occurred, a masked subliminal presentation is sufficient to elicit defensive responses to the feared stimulus (Öhman and Soares, 1994).

Thus, a rich array of experimental results demonstrates that aversive responses develop more rapidly and persist longer to fear-relevant than to fear-irrelevant natural stimuli. In addition, defensive/aversive responses can develop to natural threat stimuli even though subjects are unaware that they have seen them. Such responses make adaptive sense. Threatening events need to be responded to quickly and automatically. Pleasures can be contemplated at leisure. It is better to respond quickly and sometimes be wrong than to be slow and mostly right! The lives of our ancestors, as they pursued food and sought to avoid being food for other animals, have left a strong, negative imprint in our brains (Rozin and Royzman, 2001).

Positive Emotional Responses

Research and theory are less well developed for positive emotional responses to environmental stimuli than for negative ones. This is in part due to the fact that positive conditioning experiments are typically more difficult to conduct than aversive conditioning experiments. In addition, positive emotional responses are very complex and difficult to quantify. Nevertheless, a significant body of literature is slowly accumulating.

Symmetry and Beauty

Much evidence has been gathered on emotional responses to the symmetry of objects. A rich body of literature demonstrates that humans find symmetrical objects, including abstract patterns, woody plants, and human bodies – especially faces – aesthetically pleasing. Moreover, sexual preferences for symmetrical facial features appear to be similar across human cultures. Other vertebrates also are sensitive to very small asymmetries (see Møller and Swaddle, 1997, for a review of the human and animal literature). Conversely, asymmetries typically evoke negative emotional responses, the most extreme of which is selective infanticide of asymmetrical newborn babies in many human cultures.

There are several nonmutually exclusive reasons why positive responses to symmetry may be adaptive. One is that symmetrical animals perform better physically than asymmetrical animals, just as symmetrical objects, such as bows, arrows, axes, boats, autos, and airplanes, function better than asymmetrical ones. Asymmetrical individuals may have been exposed to severely stressful environments that disrupted normal development, thereby rendering them less functionally adequate. Alcoholic mothers give birth to children with greater developmental asymmetries than do mothers who consumed less alcohol. Thus, it is not surprising that choices of objects to use, the design of objects, and choices of social partners have evolved to favor use of and association with symmetrical objects.

Second, asymmetrical individuals are likely to have genetic defects that could be passed on to offspring. For example,

humans suffering from trisomy-21 (Down syndrome) have noticeable asymmetries due to skeletal abnormalities. Greater asymmetry in dental traits is associated with genetic disorders. Therefore, avoiding as mates asymmetrical individuals would be likely to improve the quality of an individual's offspring.

Third, because diseases can cause asymmetrical development, asymmetrical individuals may be avoided because they may currently harbor communicable disease-causing microorganisms. Good symmetry signals a long history of good health!

Habitat Selection

Habitat selection is a vital decision in the lives of all organisms. When selecting a habitat an organism responds as if it understood the significance of objects, sounds, and odors for its future survival and reproductive success. Initial responses typically are emotional feelings that lead to rejection, exploration, or a certain use of the environment. Because the strength of these responses strongly influences immediate decisions about where to settle and what to do there, the emotional responses evoked by habitats should evolve to be positively correlated with the expected survival and reproductive success of an organism in those habitats. That is, "good" habitats should evoke strong positive responses; "poor" habitats should evoke weak or even negative responses.

Multiple spatial scales are important during habitat selection. At small spatial scales, the primary decisions are whether to accept or reject a specific food item or shelter. At medium spatial scales, the key decisions concern which activity to engage in and in which patches in the environment those activities will be carried out. At still larger spatial scales, decisions center on whether to initiate major changes in where to carry out activities, that is, to migrate or to shift the base of operations.

Theoretical explorations of these decisions typically include the development of "ideal" models, that is, models that assume perfect knowledge on the part of the decision maker. These models specify the best that an organism can do in solving a problem (e.g., obtaining the most food per unit hunting time). They are unrealistic because knowledge is always incomplete, but they are valuable for assessing the marginal value of additional information and for determining how well an animal using rather simple "rules of thumb" would perform compared to an "ideal" animal. Many of these rules of thumb include aesthetic responses that guide decisions. It is useful to begin with a consideration of medium-scale responses and then turn to microscale responses.

Habitat selection, viewed at medium spatial scales, has served as a perspective for a number of studies on human aesthetic responses to landscape features (Heerwagen and Orians, 1993). During most of human evolutionary history habitats rarely provided long-term reliable resources that enabled permanent occupation of sites. Frequent moves through the landscape were the rule even though traditional sites might be revisited on an annual basis. Because relatively few generations have passed since humans began to live in mechanized and urban environments, our evolutionarily based response patterns to landscapes are unlikely to have

been substantially modified since the rise of industrialized, urban societies.

Human responses to environmental cues vary with a person's age, social status, and physiological condition. Nevertheless, positive responses to indicators of the presence of food, water, shelter, and protection from predators are widespread. So are negative responses to potential hazards, such as inclement weather, fire, dangerous predators, and barriers to movement. Although no direct evidence yet exists for genetic influences on these responses, a number of evolutionary hypotheses have generated predictions, some of which have been tested experimentally.

One approach is based on the fact that *Homo sapiens* evolved in African savannas and only recently has invaded other continents. Therefore, landscape features and tree shapes characteristic of high-quality African savannas are expected to be especially attractive to humans today. This hypothesis has been tested by determining the responses of people to tree shapes and by examining the features of "aesthetic environments," that is, those environments, such as parks and gardens, that are designed to make them attractive (Orians, 1986).

The shapes of trees that dominate savannas are good predictors of the resource-providing capacities of those environments. Therefore, people evolved to find more pleasing the shapes of trees that were prominent in environments that provided the highest-quality resources rather than shapes of trees that dominated poor-quality habitats (Coss, 2003). Trees that grow in the highest-quality African savannas have canopies that are broader than they are tall, trunks that bifurcate close to the ground, and layered canopies. People on three continents preferred Kenyan *Acacia tortilis* trees that had highly or moderately layered canopies, lower trunks, and higher canopy width/tree height ratios than trees with narrow canopies and trunks that bifurcated higher above the ground (Heerwagen and Orians, 1993). Similarly, college students in Australia, Brazil, Canada, Israel, Japan, and the United States preferred trees with broad spreading crowns over conical and columnar trees (Sommer and Summit, 1996).

Changes that landscape architects recommend to their prospective customers are another source of data on human responses to landscapes. Humphrey Repton, an eighteenth-century British landscape architect, presented his clients with "before" and "after" drawings of their estates (Repton, 1907). Because he presumably wished to encourage rather than discourage potential clients, Repton changed landscapes by creating more savanna-like scenes, by increasing visual access and penetrability of closed woods, by opening up distant views to the horizon (i.e., increased prospect), by adding refuges and cues signaling ease of movement, and by adding evidence of resource availability, particularly large mammals (Heerwagen and Orians, 1993).

Although a love of flowers is a pervasive human trait, it is not obvious why an omnivorous primate should take flowers to hospitals, bring them to dinner parties and house warmings, and annually spend billions of dollars on them. Nor is it obvious, given that flowers did not evolve their forms and colors to please us, why we should find them so aesthetically attractive. An evolutionary perspective suggests that flowers evoke strong positive feelings because they have long been associated with food resources. Flowers precede fruits, so

flowering plants provide excellent cues to timing and locations of future resources. In addition, flowers may attract animals, especially birds, that are potential human prey. In species-rich environments, paying attention to flowering plants may particularly enhance resource acquisition abilities in the future. Until the nineteenth century, honey was the only natural source of sugar; beekeeping is an ancient human enterprise.

No studies have investigated which traits of flowers evoke strong positive feelings, but the obvious changes produced in many species of flowers by artificial selection – increased size and duplication of floral parts – result in flowers similar to those that historically produced large nectar rewards. Anecdotal evidence suggests that strongly asymmetrical flowers, which usually produce large nectar rewards, are generally more attractive than symmetrical ones, suggesting a possible exception to the general human preference for symmetrical objects. Future studies of human aesthetic responses to flowers are likely to provide interesting results.

Foods and Food Selection

Eating is essential for survival. Foraging animals make two major types of decisions: what items are acceptable as food, and which acceptable items are actually eaten when encountered. Aesthetic responses are especially prominent in the first decision. The strong emotional responses associated with foods are not surprising because eating requires voluntary ingestion of foreign objects. To eat, the body's generally aversive responses designed to protect health must be overcome; vomiting and diarrhea, neither of them pleasant, are the primary post-ingestion defenses. These decisions are especially difficult for omnivores, who must ingest a variety of foods to achieve a balanced diet in varied environments where the array of available foods differs dramatically over space and time. Omnivores are expected to evolve only general food recognition mechanisms and should develop systems for classifying organisms with respect to their potential value as food.

People accept or reject foods for complex reasons (Table 3). Direct sensory responses – tastes good or tastes bad – are important, but they are only one component of acceptability. People also make decisions on the basis of anticipated consequences, both physiological and social, of eating a type of food. In addition, particular foods may

acquire ideational features that limit their acceptability to particular situations or cause them to be categorically rejected. Because of the variety of reasons that influence which foods are in the set of what is acceptable, human cuisines differ more than would be expected simply from knowing what edible resources are available in the environments in which social groups live (Rozin, 1996, 2007).

Despite the idiosyncratic nature of human diets, a few generalizations have emerged. First, most items that evoke disgust are of animal origin. Plant parts rarely evoke disgust in any culture. However, “inappropriate” items are primarily vegetable in origin (Rozin and Fallon, 1981). Disgust may be an adaptation that deterred our ancestors from eating animal tissues, such as feces, rotting meat, and soft internal parts, all of which commonly harbor large numbers of potentially harmful microorganisms. Microorganisms have the ability to multiply rapidly, so there is no safe dose for ingesting them. Disgust may represent evolutionarily programmed intuitive microbiology.

Perhaps the most interesting feature of human cuisines is the stability of the major spices and sauces that characterize them (Nabhan, 2004). Humans are remarkably conservative in their food habits and are typically reluctant to try new foods or to abandon familiar ones. Traditional flavorings are high-priority culinary items; immigrant groups go to great lengths and expense to procure them in foreign settings. The deliberate manipulation of food by adding ingredients that reliably alter its taste is a uniquely human behavior. No other animals are known to do so. Which flavorings are used probably evolved in relation to what was available in the environment, but once established they are remarkably persistent. Certain flavorings probably signal that the food is safe. For example, the French refused to eat potatoes until Parmientier, an eighteenth-century French agriculturist, showed how to prepare them in familiar ways with familiar seasonings: butter, cheese, and herbs.

Cross-cultural similarities in which spices are used exist because spices inhibit or kill food-spoiling microorganisms. The most widely used spices all have strong antimicrobial properties (Billing and Sherman, 1998); mixes of them, which are common in many traditional recipes, are even more powerful. Not surprisingly, given that disease-causing organisms are more abundant in tropical than in temperate regions, the proportion of traditional recipes containing antimicrobial spices is inversely correlated with latitude.

Table 3 Reasons people accept or reject foods

Primary reason	Examples	Rejection
A. Sensory	Tastes good	
B. Anticipated consequences		
Short-term physiological effects	No adverse reaction	Allergic reaction, gastrointestinal upsets
Long-term physiological effects	Societal concepts of “healthy foods”	Social concept of “unhealthy foods”
Social effects	Results in acceptance by group (smoking, social drinking)	Causes rejection by group (foods not eaten by that group, e.g., pigs in some Mideast cultures)
C. Ideational		
Appropriateness	Appropriate ritual foods	Inappropriate nonedible contaminants (soil, weeds)

Source: Modified from Rozin P and Fallon A (1981) A perspective on disgust. *Psychological Review* 94: 23–41.

Alternative hypotheses – that spices provide micronutrients, disguise the taste and smell of spoiled foods, or increase perspiration and, thus, evaporative cooling – are not supported by the extensive data base (Billing and Sherman, 1998).

Restorative Responses

If aesthetic responses evolved because they enabled people to better solve life's problems, exposure to high-quality environments should be restorative, that is, it should reduce feelings of tension and stress. Stress reduction consistently emerges as one of the key benefits reported by recreationists in wilderness areas. Restoration from stress is also reported as a key benefit from time spent in urban parks with savanna-like vegetation and water (Schroeder, 1989). Patients recovering from surgery in hospitals with either views of natural vegetation or simulated views that depict natural scenes with water recover more rapidly and have less postoperative anxiety than patients with no access to natural views or who are presented with simulations of abstract designs. Many studies have shown that even a brief exposure to nature, real or *via* photographs, leads to positive emotional feelings, reductions in stress, and better performance on demanding tasks (see Ulrich, 1995, for a review). Clearly, the people's affiliative responses to nature have important implications for the design of work and living spaces and healthcare facilities that are just beginning to be implemented.

Aesthetics and Biodiversity

Although people are strongly attracted to living organisms, relationships between the attractiveness of an environment and the number of species in it are unclear. On the one hand, for example, the most highly evolved garden traditions – European formal gardens and Japanese gardens – are based on just a few species of woody plants. Landscape designers generally do not like the gardens of botanists because they are cluttered up with plants of too many species! Scenes of environments that contain a jumble of plants of many species receive low scores in psychological tests. People report that they are too difficult to interpret; it is difficult to determine how to enter and use them.

On the other hand, people take great pleasure in finding as many species of birds as they can on a given day and from assembling "life lists" of species they have seen. Generally, seeing more species is better than seeing fewer species. Journeys of hundreds or even thousands of miles to see a rare species not on one's life list are not uncommon in today's mobile society. People are also powerfully attracted to the unusual – rare species, individuals outside the normal range of the species, or individuals present at unusual times of the year or in unusual habitats.

Because these familiar patterns of human behavior have been subjected to remarkably little formal study, we can only speculate about why they have evolved. That environments with intermediate levels of biological complexity should be preferred over both simpler and more complex environments makes sense, because the range of resources present in an

environment and the ability to find and use those resources probably peak at intermediate levels of complexity. Simple environments have too few resources; complex ones have so many that choosing among them becomes difficult. Developing a suitable classification system to guide responses to the components of complex environments may be especially difficult. People may have evolved to respond to rare and unusual events because they provide new information about the state of the environment. Not all novel events are associated with something important, but it may be best to pay attention to them to find out if they are rather than to ignore the signals. Novel events may indicate that current patterns of environmental use should be altered.

Aesthetics and Cognition

The human mind evolved into its current form long before the invention of agriculture and the dawn of the Industrial Revolution. It evolved its special characteristics in the service of our hunter-gatherer ancestors, who almost daily faced serious challenges from their physical, biological, and social environments. During the past century, many scientists found it difficult to explain why the demands of functioning in a preagricultural environment should have favored the evolution of the vast complexities of the human mind, which is capable of the many feats of which we are so proud. The apparent paradox arises because of a failure to appreciate that succeeding as a forager is probably more complicated than playing chess or doing calculus. To outwit nature, people need to use some form of intuitive scientific thinking, develop abstract conceptions, think about the future, compete in a rich social environment, and plan tactics. Aesthetic responses are basic components in all of these responses.

Mathematicians describe their search for important theorems as an aesthetic experience; they think of proven theorems as being beautiful. In fact, scientists in all fields regularly describe their models, experiments, and results in aesthetic terms. Thus, aesthetic sensibilities are imbedded deep in the human mind, having evolved in the service of choice of mates, habitats, and foods. An aesthetic sense functions as a holistic filter that helps the mind search efficiently for good solutions. It can do this because the filter has been molded by countless evolutionary experiences. Perhaps one of the most satisfying results of having a mind that was molded by natural selection is that we generally enjoy doing things that are good for us to do.

Glossary

Ad-Hoc Open-ended Working Group on Review of Implementation A Convention body established to consider progress in the implementation of the Convention, to review the impacts and effectiveness of existing processes under the Convention, national focal points and the Secretariat, as part of the overall process for improving the operations of the Convention.

Aichi Biodiversity Targets Twenty internationally-agreed outcome-oriented targets included in the Strategic Plan for Biodiversity 2011–2020 setting the agenda for achievements at the global level and providing a framework for the establishment of national or regional targets.

Article 8(j) An article of the text of the Convention which calls for the respect, preservation and maintenance of knowledge, innovations and practices of indigenous and local communities embodying traditional lifestyles relevant for the conservation and sustainable use of biological diversity.

Biodiversity The Convention on Biological Diversity defines biodiversity as the variability among living organisms from all sources including, inter alia, terrestrial, marine and other aquatic ecosystems, and the ecological complexes of which they are part; this includes diversity within species, between species, and of ecosystems.

Conference of the Parties The Conference of the Parties is the governing body of the Convention on Biological Diversity, and advances implementation of the Convention through the decisions it takes at its periodic meetings. It is composed of the countries that are Party to the Convention.

Convention on Biological Diversity The Convention on Biological Diversity is a framework for national and cooperative action for the conservation of biodiversity, the sustainable use of its components, and the equitable sharing of benefits arising out of the utilization of genetic resources. It requires contracting Parties to ensure that actions to achieve its objectives are undertaken at all levels and in all sectors, in a coordinated and crosscutting fashion.

Ecosystem approach A strategy for the integrated management of land, water and living resources that promotes conservation and sustainable use in an equitable way. It is based on the application of appropriate scientific methodologies focused on levels of biological

organization which encompass the essential processes, functions and interactions among organisms and their environment. It recognizes that humans, with their cultural diversity, are an integral component of ecosystems.

Global Biodiversity Outlook The flagship publication of the Convention on Biological Diversity and currently in its third edition. The Outlook draws on a range of information to summarize the status and trends of biodiversity and draws conclusions for the further implementation of the Convention.

Global Environment Facility The financial mechanism of the Convention on Biological Diversity which provides grants to developing countries and countries with economies in transition for projects which benefit the global environment.

National Biodiversity Strategies and Action Plans The process by which countries can plan to address the threats to their biodiversity and implement the Convention on Biological Diversity and related instruments.

Party A country that has ratified, acceded to, approved or accepted the Convention is considered a Party to it.

Programmes of Work Programmes of Work establish a vision for, and basic principles to guide work under the Convention by setting out key issues for consideration, identifying potential outputs and means for achieving these.

Strategic Plan for Biodiversity 2011–2020 The Strategic Plan promotes the coherent and effective implementation of the three objectives of the Convention on Biological Diversity and serves as a flexible framework for the establishment of national and regional targets.

Subsidiary Body on Scientific, Technical and Technological Advice (SBSTTA) An intergovernmental scientific advisory body that provides the Conference of the Parties to the Convention on Biological Diversity and its other subsidiary bodies with advice relating to the implementation of the Convention. Multidisciplinary and open to participation by all Parties, SBSTTA comprises government representatives competent in the relevant field of expertise.

Thipping points A situation in which an ecosystem experiences a shift to a new state, with significant changes to biodiversity and the services to people it underpins, at a regional or global scale.

Introduction

The Convention on Biological Diversity (CBD) is the key international treaty for the conservation and sustainable use of biodiversity and for the fair and equitable sharing of the benefits arising out of the use of genetic resources. One-hundred and ninety-two countries, and the European Union

are Party to the Convention which is implemented primarily through action at the national level. The governing body of the Convention reviews implementation and develops policy to guide national implementation and promote international cooperation. Two main subsidiary legal agreements have been adopted under the convention: the Cartagena Protocol on Biosafety and the Nagoya Protocol on Access and Benefit

Sharing. In 2010, a new Strategic Plan for Biodiversity 2011–2020 was adopted, providing a 10-year framework of action by all stakeholders. The Plan includes 20 outcome-oriented Aichi Biodiversity Targets. The major challenges for the implementation of the Plan relate to the need to address the pressures on biodiversity and the underlying causes of biodiversity loss by mainstreaming biodiversity across government and society.

The CBD: Main Instruments

Concern over the rapid loss of biodiversity and the realization that it plays a fundamental role in supporting human life motivated the creation of the CBD, a legally binding global treaty. Opened for signature at the Earth Summit in Rio de Janeiro in 1992 and entering into force in 1993, the Convention arose from an international dialogue begun a decade earlier by the World Commission on Environment and Development (known as the Brundtland Commission).

The word biodiversity, a contraction of the synonymous phrase “biological diversity”, is defined by the CBD as “the variability among living organisms from all sources including, *inter alia*, terrestrial, marine and other aquatic ecosystems and the ecological complexes of which they are part; this includes diversity within species, between species and of ecosystems” (United Nations, 1992). As such the Convention is holistic, covering all aspects of biodiversity, and was the first international treaty to acknowledge the role of biodiversity in sustainable development.

The Convention objectives are “the conservation of biological diversity, the sustainable use of its components and the fair and equitable sharing of the benefits arising out of the utilization of genetic resources, including by appropriate access to genetic resources and by appropriate transfer of relevant technologies, taking into account all rights over those resources and to technologies, and by appropriate funding.” The Convention is composed of 42 Articles that provide for principles (e.g., sovereign rights over national resources and the responsibility to ensure that activities within their jurisdiction or control do not cause damage to the environment of other States or of areas beyond the limits of national jurisdiction), substantive obligations (e.g., for *in situ* and *ex situ* conservation, respect for indigenous knowledge, sustainable use, use of environmental impacts assessment, use of incentive measures) and procedural arrangements (e.g., meetings of the governing body and the operations of its Secretariat). These articles form the basis of the structure and function of the Convention.

The Convention on Biological Diversity has near-universal participation of countries and is recognized by the United Nations General Assembly as the primary international instrument for biodiversity. To date, 192 countries and the European Union have ratified the Convention, constituting the 193 Parties. These form the governing body of the Convention referred to as the Conference of the Parties (COP) which meets periodically (currently, every 2 years). The United States which has signed the Convention but not yet ratified it, participates as an observer. International organizations and

representatives of indigenous and local communities and civil society also participate in the work of the Convention.

The Conference of the Parties reviews implementation of the Convention on the basis of national reports and the Global Biodiversity Outlook – a periodic publication that assesses the state of biodiversity, actions taken under the Convention to achieve its objectives and future prospects for biodiversity (see The Global Biodiversity Outlook: Assessing Progress and Providing the Basis for Future Action). The COP also advances implementation of the Convention through the decisions it takes at its periodic meetings. In its first 10 meetings, the Conference of the Parties has taken a total of 299 decisions. Among these are key decisions that outline the major areas of work of the Convention, establish principles and guidelines for action, and set out a plan for the more effective and coherent implementation of the Convention as a whole (see The CBD Regime: Supporting Action at the International Level).

The Conference of the Parties has held 10 ordinary meetings, and 1 extraordinary meeting (the latter, to adopt the Cartagena Protocol on Biosafety (see Box 1) was held in two parts). At its 10th meeting, the Conference of the Parties adopted the Nagoya Protocol on Access to Genetic Resources and the Fair and Equitable Sharing of Benefits Arising from their Utilization (see Box 2). The 11th meeting of the Conference of the Parties takes place in Hyderabad, India, in October 2012.

The Conference of the Parties is supported by several additional Convention bodies. One of these bodies is an open-ended intergovernmental scientific advisory body known as the Subsidiary Body on Scientific, Technical and Technological Advice (SBSTTA). SBSTTA comprises government representatives of all Parties as well as observers and its functions

Box 1 Cartagena Protocol on Biosafety to the CBD

The Cartagena Protocol on Biosafety to the CBD is an international treaty governing the movements from one country to another of living modified organisms resulting from modern biotechnology (more commonly known as genetically modified organisms). It was adopted on 29 January 2000 as a supplementary agreement to the CBD and entered into force on 11 September 2003. As of the end of 2011, there are 162 Parties to the Protocol.

The Protocol establishes an advance informed agreement procedure for ensuring that countries are provided with the information necessary to make informed decisions before agreeing to the import of such organisms into their territory. The Protocol contains reference to a precautionary approach and reaffirms the precaution language in Principle 15 of the Rio Declaration on Environment and Development. The Protocol also establishes a Biosafety Clearing-House to facilitate the exchange of information on living modified organisms and to assist countries in the implementation of the Protocol.

During a meeting of the governing body of the Cartagena Protocol on Biosafety (known as the COP serving as the meeting of the Parties to the Protocol), a new international treaty, the Nagoya – Kuala Lumpur Supplementary Protocol on Liability and Redress to the Cartagena Protocol on Biosafety, was adopted. The supplementary Protocol provides international rules and procedure on liability and redress for damage to biodiversity resulting from living modified organisms. The new treaty will enter into force 90 days after being ratified by at least 40 Parties to the Cartagena Protocol on Biosafety.

Box 2 Access to Genetic Resources and the Fair and Equitable Sharing of Benefits Arising from their Utilization: the Convention and the Nagoya Protocol

The principles governing access to genetic resources and the fair and equitable sharing of benefits

In its article 15, the Convention reaffirms national sovereignty over natural resources and establishes that the right to determine access to genetic resources rests with national governments and is subject to national legislation. At the same time, the Convention requires Parties to facilitate access and “not to impose restrictions that run counter to the objectives of the Convention.” Article 15 introduces two key concepts: access shall be on “mutually agreed terms” (MAT) and subject to “prior informed consent” (PIC).

For access to be on MAT, both supplier and recipient must agree to the terms, thus providing an opportunity for the providing country to negotiate a share of the benefits derived from the use of the genetic resources. Usually, this implies a contractual arrangement, executed on a bilateral basis. The contract often takes the form of a “Material Transfer Agreement” (MTA) setting out the agreed terms on which the genetic material is transferred. The MTA may specify the permitted or prohibited uses of the genetic resources provided, including whether or not it may be commercialized; any rights which may or may not be taken out over the resource or its derivatives; and the benefits that are to be shared.

Unless the Party determines otherwise, access is also subject to PIC. This means that the responsible authority of the providing country can decide to grant or refuse access following a request from the applicant. In the application, the applicant may be required to provide information concerning the genetic resources required and the purpose for which they are required, as well as any proposal for benefit sharing. As part of the PIC procedure, the responsible authority may consult with indigenous and local communities, or other stakeholders, concerned.

The Nagoya Protocol on Access to Genetic Resources and the Fair and Equitable Sharing of Benefits Arising from their Utilization to the Convention on Biological Diversity

The Nagoya Protocol on Access and Benefit Sharing is a supplementary agreement to the CBD. It provides a transparent legal framework for the effective implementation of one of the three objectives of the CBD: the fair and equitable sharing of benefits arising out of the utilization of genetic resources.

The Nagoya Protocol was adopted on 29 October 2010 in Nagoya, Japan, and will enter into force 90 days after the 50th instrument of ratification is received. Its objective is the fair and equitable sharing of benefits arising from the utilization of genetic resources, thereby contributing to the conservation and sustainable use of biodiversity. The Nagoya Protocol will create greater legal certainty and transparency for both providers and users of genetic resources by establishing more predictable conditions for access to genetic resources and by helping to ensure benefit-sharing when genetic resources leave the contracting party providing the genetic resources. The Nagoya Protocol applies to genetic resources that are covered by the CBD, and to the benefits arising from their utilization. The Nagoya Protocol also covers traditional knowledge associated with genetic resources that are covered by the CBD and the benefits arising from its utilization.

By helping to ensure benefit-sharing, the Nagoya Protocol creates incentives to conserve and sustainably use genetic resources, and therefore enhances the contribution of biodiversity to development and human well-being. The Protocol sets out core obligations related to access, benefit sharing, and compliance for its contracting Parties.

include providing assessments of the status of biological diversity, providing assessments of the types of measures taken in accordance with the provisions of the Convention, and responding to questions that the COP may put to the body. By mid 2012, SBSTTA had met 16 times.

The COP is further supported by the Ad Hoc Open-ended Working Group on Review of Implementation of the Convention. The Working Group is another intergovernmental body and was established to consider progress in the implementation of the Convention and to review the impacts and effectiveness of existing processes under the Convention. By mid 2012, the Working Group on the Review of Implementation had met four times. Another Ad Hoc Open-ended Working Group addresses Article 8(j) of the Convention and its related provisions which call for the respect, preservation and maintenance of the knowledge, innovations and practices of indigenous and local communities relevant to the conservation and sustainable use of biodiversity and serves to help reflect these in the Convention.

The Convention's broad scope makes translating its provisions into policy and practice extremely challenging. In the first 10 years following its entry into force, the Conference of the Parties has developed a comprehensive body of guidance relating to the conservation and sustainable use of biodiversity and the equitable sharing of the benefits from the use of genetic resources. The new Strategic Plan for Biodiversity 2011–2020 and the Aichi Biodiversity Targets (*see* The Strategic Plan for Biodiversity 2011–2020 and the Aichi Biodiversity Targets) provide an agreed framework for implementation of the

Convention through this decade. It superseded the earlier strategic plan and the “2010 Biodiversity Target”. The major challenge now is to ensure implementation of the Convention and the decisions of the Conference of the Parties in order to achieve the Aichi Targets. This requires increased commitment from Parties, enhanced technical and scientific cooperation and the mobilization of additional financial resources. To ensure progress, the Conference of the Parties will need to review implementation more effectively than in the past.

The Convention on Biological Diversity is supported by a Secretariat based in Montreal, Canada since 1996. As a neutral organization staffed by international civil servants, the Secretariat is accountable to the COP and its subsidiary. Its head, the Executive Secretary, is appointed by the Secretary-General of the United Nations in consultation with the Parties to the Convention.

The Secretariat assists and provides administrative support to the COP and other Convention bodies. It represents the day-to-day focal point for the Convention, organizes all meetings under the Convention, prepares background documentation for those meeting and facilitates the flow of authoritative information on the implementation of the Convention. The Secretariat plays a significant role in coordinating the work carried out under the Convention with that of other relevant institutions and conventions, and represents the Convention at meetings of relevant bodies. The Secretariat also facilitates support to Parties for the implementation of the Convention, for example, by providing technical and practical guidelines and by organizing capacity-building activities.

The Global Biodiversity Outlook: Assessing Progress and Providing the Basis for Future Action

In 2002, the Conference of the Parties adopted a Strategic Plan. Specifically Parties committed themselves “to a more effective and coherent implementation of the three objectives of the Convention, to achieve by 2010 a significant reduction of the current rate of biodiversity loss at the global, regional and national level as a contribution to poverty alleviation and to the benefit of all life on earth”. This target came to be known as the 2010 Biodiversity Target and was subsequently endorsed by heads of state and government at the World Summit on Sustainable Development in Johannesburg, 2002, and by the United Nations General Assembly. It was also incorporated as a new target under one of the Millennium Development Goals – Ensure Environmental Sustainability. The 2010 biodiversity target therefore represented a commitment from all governments; including those not party to the CBD.

The third edition of the Global Biodiversity Outlook (GBO-3), published in 2010, assessed progress toward the 2010 Biodiversity Target. In its final assessment it found that the 2010 biodiversity target had not been met despite an increase in conservation efforts. It concluded that globally the state of biodiversity continued to decline, according to most indicators, largely because the pressures on biodiversity continue to increase. It also found that there was neither indication of a significant reduction in the rate of decline in biodiversity, nor of a significant reduction in pressures on it (see Box 3). However, it also observed that there were several indications that responses to biodiversity loss were increasing and improving, although not yet on a scale sufficient to affect the overall negative trends in the state of biodiversity or the pressures on it.

The continued decline of biodiversity risks pushing the Earth’s ecosystems beyond certain thresholds or tipping points

Box 3 Biodiversity Indicators

There is no single measurement that captures the current status or trends in global biodiversity. Owing to its complexity a range of indicators has been developed by the CBD to provide scientifically rigorous assessments of trends in the state of the various components of biodiversity. The Convention adopted a set of 15 headline indicators which relate to the different components of biodiversity (genes, populations, species, and ecosystems) as well as the pressures being imposed on it and the responses being adopted to address biodiversity loss.

The GBO-3 found that 10 of the 15 headline indicators show trends unfavourable for biodiversity. Overall the state of biodiversity shows negative trends, with no significant reduction in the rate of decline. There is no evidence of a slowing in the increase of pressures on biodiversity, based on the trend shown by indicators of humanity’s ecological footprint, nitrogen deposition, alien species introductions, overexploited fish stocks and the impact of climate change on biodiversity. In contrast, all indicators of the responses to address biodiversity loss are moving in a positive direction. More areas are being protected for biodiversity, more policies and laws are being introduced to avoid damage from invasive alien species, and more money is being spent in support of the CBD and its objectives. The overall message from these indicators is that despite the many efforts taken around the world to conserve biodiversity and use it sustainably, responses so far have not been adequate to address the scale of biodiversity loss or reduce the pressures (Figure 1).

(see Box 4). A tipping point refers to a situation in which an ecosystem experiences a shift to a new state, with significant changes to biodiversity and the services to people it underpins, at a regional or global scale. Tipping points are a major concern for scientists, managers, and policy-makers, because of their potentially large impacts on biodiversity, ecosystem services, and human well-being. It can be extremely difficult for societies to adapt to rapid and potentially irreversible shifts in the functioning and character of an ecosystem on which they depend (Leadley *et al.*, 2010; Pereira *et al.*, 2011). While it is highly likely that tipping points will occur in the future if effective action to protect biodiversity is not taken, the dynamics in most cases cannot yet be predicted with precision. Accordingly, to avoid tipping points a precautionary approach is warranted.

The Global Biodiversity Outlook arrived at the following conclusions. These guided the development of the Convention’s new strategic plan:

- There are greater opportunities than previously recognized to address the biodiversity crisis while contributing to other social objectives.
- Well-targeted policies focusing on critical areas, species, and ecosystem services are essential to avoid the most

Box 4 Examples of Tipping Points

There is a high risk of dramatic biodiversity loss and accompanying degradation of a broad range of ecosystem services if ecosystems are pushed beyond certain thresholds or tipping points. The poor would face the earliest and most severe impacts of such changes, but ultimately all societies and communities would suffer. Examples include:

The Amazon forest, due to the interaction of deforestation, fire and climate change, could undergo a widespread dieback, with parts of the forest moving into a self-perpetuating cycle of more frequent fires and intense droughts leading to a shift to savanna-like vegetation. While there are large uncertainties associated with these scenarios, it is known that such dieback becomes much more likely to occur if deforestation exceeds 20–30% (it is currently above 17% in the Brazilian Amazon). It would lead to regional rainfall reductions, compromising agricultural production. There would also be global impacts through increased carbon emissions, and massive loss of biodiversity.

The build-up of phosphates and nitrates from agricultural fertilizers and sewage effluent can shift freshwater lakes and other inland water ecosystems into a long-term, algae-dominated (eutrophic) state. This could lead to declining fish availability with implications for food security in many developing countries. There will also be loss of recreation opportunities and tourism income, and in some cases health risks for people and livestock from toxic algal blooms. Similar, nitrogen-induced eutrophication phenomena in coastal environments lead to more oxygen-starved dead zones, with major economic losses resulting from reduced productivity of fisheries and decreased tourism revenues.

The combined impacts of ocean acidification, warmer sea temperatures, and other human-induced stresses make tropical coral reef ecosystems vulnerable to collapse. More acidic water – brought about by higher carbon dioxide concentrations in the atmosphere – decreases the availability of the carbonate ions required to build coral skeletons. Together with the bleaching impact of warmer water, elevated nutrient levels from pollution, overfishing, sediment deposition arising from inland deforestation, and other pressures, reefs worldwide increasingly become algae-dominated with catastrophic loss of biodiversity and ecosystem functioning, threatening the livelihoods and food security of hundreds of millions of people.

Figure 1 These graphs illustrate that the state of biodiversity is declining and the pressures on it are increasing but that our responses to its loss are also increasing. Reproduced from [Secretariat of the Convention on Biological Diversity \(2010a\) Action for Biodiversity: Towards a Society in Harmony with Nature](#). Secretariat of the Convention on Biological Diversity; [Secretariat of the Convention on Biological Diversity \(2010b\) Global Biodiversity Outlook 3](#), pp. 8–13. Secretariat of the Convention on Biological Diversity; Based on [Butchart SHM, Walpole M, Collen B, et al. \(2010\) Global biodiversity: Indicators of recent declines. Science 328\(5982\): 1164–1168.](#)

dangerous impacts on people and societies. Preventing further human-induced biodiversity loss for the near-term future will be extremely challenging, but biodiversity loss may be halted and in some aspects reversed in the longer term, if urgent, concerted and effective action is initiated now in support of an agreed long-term vision. While some actions may entail moderate costs or tradeoffs, the gains for biodiversity can be large in comparison.

- Such action to conserve biodiversity and use its components sustainably will reap rich rewards – through better health, greater food security, less poverty and a greater capacity to cope with, and adapt to, environmental change.

In fact, placing greater priority on biodiversity is central to the success of development and poverty-alleviation measures.

- The linked challenges of biodiversity loss and climate change must be addressed by policymakers with equal priority and in close coordination, if the most severe impacts of each are to be avoided.
- Better protection of biodiversity should be seen as a prudent and cost-effective investment in risk-avoidance for the global community.
- Scientific uncertainty surrounding the precise connections between biodiversity and human well-being, and the

functioning of ecosystems, should not be used as an excuse for inaction.

- Effective action to address biodiversity loss depends on addressing the underlying causes or indirect drivers of that decline. This will mean: much greater efficiency in the use of land, energy, fresh water and materials to meet growing demand; use of market incentives, and avoidance of perverse subsidies to minimize unsustainable resource use and wasteful consumption; strategic planning in the use of land, inland waters and marine resources to reconcile development with conservation of biodiversity and the maintenance of multiple ecosystem services. While some actions may entail moderate costs or tradeoffs, the gains for biodiversity can be large in comparison; and ensuring that the benefits arising from use of and access to genetic resources and associated traditional knowledge, for example, through the development of drugs and cosmetics, are equitably shared with the countries and cultures from which they are obtained. Enhanced efforts are also needed in the areas of communication, education, and awareness-raising to ensure that as far as possible, everyone understands the value of biodiversity and what steps they can take to protect it, including through changes in personal consumption and behaviour.
- Urgent action is needed to reduce the direct drivers of biodiversity loss. The application of best practices in agriculture, sustainable forest management and sustainable fisheries should become standard practice, and approaches aimed at optimizing multiple ecosystem services instead of maximizing a single one should be promoted. In many cases, multiple drivers are combining to cause biodiversity loss and degradation of ecosystems. Sometimes, it may be more effective to concentrate urgent action on reducing those drivers most responsive to policy changes. This will reduce the pressures on biodiversity and protect its value for human societies in the short to medium-term, while the more intractable drivers are addressed over a longer time scale. For example, the resilience of coral reefs – and their ability to withstand and adapt to coral bleaching and ocean acidification – can be enhanced by reducing overfishing, land-based pollution, and physical damage.
- Increasingly, restoration of terrestrial, inland water and marine ecosystems will be needed to reestablish ecosystem functioning and the provision of valuable services.
- The action taken over the next decade or two, and the direction charted under the CBD, will determine whether the relatively stable environmental conditions on which human civilization has depended for the past 10,000 years will continue beyond this century. If we fail to use this opportunity, many ecosystems on the planet will move into new, unprecedented states in which the capacity to provide for the needs of present and future generations is highly uncertain.

The Strategic Plan for Biodiversity 2011–2020 and the Aichi Biodiversity Targets

At the 10th meeting of the Parties to the CBD, in 2010 in Nagoya, Japan, the Parties considered the conclusions of the GBO-3 and adopted a new Strategic Plan with the purpose of

inspiring broad-based action in support of biodiversity over the next decade by all countries and stakeholders (Box 5). The Strategic Plan for Biodiversity 2011–2020 is an overarching framework on biodiversity, not only for the biodiversity-related conventions, but also for the entire United Nations system. The Strategic Plan is based on more than 2 years of consultation with Governments and stakeholders, experience in implementation the Convention, as well the conclusions of the GBO-3.

The Strategic Plan is comprised of a shared vision, a mission, and five strategic goals under which 20 ambitious yet achievable targets, known as the Aichi Biodiversity Targets, are organized. The goals and targets comprise both aspirations for achievement at the global level, and a flexible framework for the establishment of national or regional targets. In adopting the Plan Parties committed themselves to setting their own targets within this flexible framework, taking into account national needs and priorities, while also bearing in mind national contributions to the achievement of the global targets.

The Strategic Plan for Biodiversity 2011–2020 will be implemented primarily through activities at the national or subnational level, with supporting action at the regional and global levels. The Programmes of Work on various biomes and crosscutting issues that have been developed under the Convention, and formalized by decisions of the Conference of the Parties, provide detailed guidance on the types of actions and considerations which should be taken to implementation of the Strategic Plan. For the implementation of the Strategic Plan there is a need to broaden political support for the Convention and biodiversity more generally, and to integrate the biodiversity agenda into the plans and policies of other sectors across government, the economy and society.

Progress toward the implementation of the Strategic Plan will be reported by Parties through national reports that they provide to the CBD on a regular basis. Specifically Parties have been asked to provide information on any national targets, commitments, and/or policy instruments they adopt to implement the Strategic Plan, as well as any milestones toward these targets. This information will be considered by the Conference of the Parties at its 11th and subsequent meetings.

National Implementation of the Convention

While the CBD is an international environmental agreement it is primarily implemented through national level action. National biodiversity strategies and action plans (NBSAPs) are the principal instruments for implementing the Convention at the national level. NBSAPs reflect how a country intends to fulfill the objectives of the Convention in light of specific national circumstances, and the steps it plans on taking. The Convention requires countries to prepare a national biodiversity strategy (or equivalent instrument) and to ensure that this strategy is mainstreamed into the planning and activities of all those sectors whose activities can have an impact (positive and negative) on biodiversity.

By the end of 2011, 175 countries and the European Union (over 90% of the total Parties to the Convention) had developed their NBSAPs or equivalent instruments and were implementing them. Some 40 Parties have revised their

Box 5 The Strategic Plan for Biodiversity 2011–2020 and the Aichi Biodiversity Targets

Vision

The vision for the new plan is: "Living in Harmony with Nature" where "By 2050, biodiversity is valued, conserved, restored and wisely used, maintaining ecosystem services, sustaining a healthy planet and delivering benefits essential for all people."

Mission

The mission of the new plan is to "take effective and urgent action to halt the loss of biodiversity in order to ensure that by 2020 ecosystems are resilient and continue to provide essential services, thereby securing the planet's variety of life, and contributing to human well-being, and poverty eradication. To ensure this, pressures on biodiversity are reduced, ecosystems are restored, biological resources are sustainably used and benefits arising out of utilization of genetic resources are shared in a fair and equitable manner; adequate financial resources are provided, capacities are enhanced, biodiversity issues and values mainstreamed, appropriate policies are effectively implemented, and decision-making is based on sound science and the precautionary approach."

Aichi Biodiversity Targets (*The text of the targets in this box has been abridged. For the full official text, please refer to www.cbd.int/sp*)

Strategic Goal A: Address the Underlying Causes of Biodiversity Loss

- Target 1 – People are aware of the values of biodiversity and the steps they can take to conserve and use it sustainably.
- Target 2 – Biodiversity values have been integrated into national and local development and poverty reduction strategies and planning processes.
- Target 3 – Incentives, including subsidies, harmful to biodiversity are eliminated, phased out or reformed and positive incentives are developed and applied.
- Target 4 – Governments, business and stakeholders at all levels have taken steps to achieve or have implemented plans for sustainable production and consumption.

Strategic Goal B: Reduce the Direct Pressures on Biodiversity and Promote Sustainable Use

- Target 5 – The rate of loss of all natural habitats is at least halved and where feasible brought close to zero.
- Target 6 – Overfishing is avoided and fisheries have no significant adverse impacts on threatened species and vulnerable ecosystems.
- Target 7 – Areas under agriculture, aquaculture, and forestry are managed sustainably.
- Target 8 – Pollution, including from excess nutrients, has been brought to levels that are not detrimental to ecosystem function and biodiversity.
- Target 9 – Invasive alien species and pathways are identified, priority species are controlled or eradicated, and measures are in place to manage pathways.
- Target 10 – The multiple anthropogenic pressures on vulnerable ecosystems impacted by climate change or ocean acidification are minimized.

Strategic Goal C: To improve the Status of Biodiversity by Safeguarding Ecosystems, Species and Genetic Diversity

- Target 11 – At least 17% of terrestrial and inland water, and 10% of coastal and marine areas are conserved through effective, ecologically representative and well connected systems of protected areas.
- Target 12 – The extinction of known threatened species has been prevented and their conservation status, particularly of those most in decline, has been improved and sustained.
- Target 13 – The genetic diversity of cultivated plants and farmed and domesticated animals and of wild relatives is maintained.

Strategic Goal D: Enhance the Benefits to All from Biodiversity and Ecosystem Services

- Target 14 – Ecosystems that provide essential services are restored and safeguarded.
- Target 15 – Ecosystem resilience and the contribution of biodiversity to carbon stocks has been enhanced, through conservation and restoration, including restoration of at least 15% of degraded ecosystems.
- Target 16 – The Nagoya Protocol on Access and Benefit Sharing is in force and operational.

Strategic Goal E: Enhance Implementation through Participatory Planning, Knowledge Management and Capacity Building

- Target 17 – Each Party has developed, adopted as a policy instrument, and has commenced implementing an effective, participatory and updated national biodiversity strategy and action plan.
- Target 18 – Traditional knowledge, innovations and practices of indigenous and local communities, and their customary use of biological resources, are respected.
- Target 19 – Knowledge relating to biodiversity is improved, shared and transferred, and applied.
- Target 20 – The mobilization of financial resources for implementing the Strategic Plan for Biodiversity 2011–2020 increased substantially from the current levels.

NBSAPs, and most others are in the process of doing so, in the light of the new Strategic Plan for Biodiversity 2011–2020. Among other things, revisions allow Parties to identify and meet new challenges and to respond to recent guidance from the Conference of the Parties. Moreover, biodiversity planning is, of necessity, an ongoing process and updating national strategies allows the main actors to learn from experience and improve their policies and activities to implement the Convention.

While a few countries (e.g., Costa Rica, Samoa, Saint Lucia) have implemented most of the activities proposed in their national strategies, the level of implementation of the “first generation” of national strategies was estimated to be in the range of only 30–40%. The main obstacles to implementation reported by countries include: limited financial, technical and human resources and capacities, limited information, low political will, lack of coordination between ministries, poverty, low awareness level of biodiversity issues, and limited incentives for biodiversity conservation and sustainable use. Nonetheless, new legislation has been developed, institutions strengthened and many activities for biodiversity conservation and use carried out (*Secretariat of the Convention on Biological Diversity, 2010a*). For example, specific biodiversity laws and policies in Brazil, Costa Rica, Japan, Norway, and South Africa have established the institutional framework for coordinated implementation of the Convention in those countries.

NBSAPs have catalysed action in a broader range of issues such as: invasive alien species (beyond those already addressed through plant protection services in the agricultural and forest sectors); sustainable use; incentive measures; protection of traditional knowledge; access and benefit-sharing; biosafety; and agricultural biodiversity. There appears to have been an evolution in the scope and strategic focus of national biodiversity strategies and action plans; recently developed and updated ones tend to be more strategic than the first generation of national biodiversity strategies and action plans and have a stronger emphasis on the mainstreaming of biodiversity into other sectors and cross-sectoral plans and policies (*Prip and Gross, 2010*).

Mainstreaming of biodiversity needs to take place at various levels: integration into cross-sectoral policies and strategies (finance, national development, poverty eradication); integration of biodiversity into economic sectors (including through different government ministries); and integration into spatial planning, at all levels of government, especially at provincial/state and municipal levels.

To be effective, NBSAPs must reflect broader national development and environment objectives. For example, the Namibian NBSAP is positioned as a contribution to National Development and Vision 2030, and Rwanda has integrated biodiversity issues into its Economic Development and Poverty Reduction Strategy. A number of recently developed or updated NBSAPs are closely linked with the cycle of national planning processes such as 5-year plans (e.g., Indonesia, Malaysia, Thailand), poverty reduction plans (Cambodia, Madagascar, Vietnam), the framework for achievement of the Millennium Development Goals (Cambodia), and development plans (Namibia, Philippines). In Indonesia, the planning authority led the development of the NBSAP which

facilitated the later incorporation of the NBSAP into the Medium-Term Development Plan.

Many countries report the integration of biodiversity into the tourism, forestry and agricultural sectors. The integration of biodiversity into other sectors is less common. For example, France has developed sectoral action plans to implement the NBSAP through various ministries. Rwanda reports that it has successfully mainstreamed biodiversity in other sectors besides the environment, such as agriculture, education, health, rural development, forestry, mining, tourism, finance, trade and industry. Most countries are promoting biodiversity activities related to climate change adaptation, and an increasing number of them are taking actions related to climate change mitigation. For example, Samoa’s National climate change adaptation program of action recognizes the importance of coral reefs and mangroves in the protection of coastal assets and the plan provides for the establishment of marine and terrestrial conservation areas.

Nearly all countries have laws and mechanisms in place for environmental impact assessment and about one-third of them have policies related to strategic environmental impact assessment. Both figures represent an increase from the situation 5 years previously. Many countries are integrating biodiversity into mechanisms for spatial planning. Brazil has promoted Ecological-Economical Zoning processes at federal, state, and municipal levels as well as for some hydrological basins. South Africa has carried out a national spatial assessment of biodiversity and is integrating biodiversity into spatial planning and economic development at the municipal level in North West and Western Cape Provinces.

The use of economic instruments is seen as an important – but under-used – approach to mainstream biodiversity. Some countries such as Mexico are integrating biodiversity-related issues into national accounts. South Africa has adopted amendments to the tax legislation, effective from 2009, under which specified conservation costs are tax deductible. For example, expenses incurred as a result of controlling alien and invasive vegetation are to be allowed as a deduction for farming purposes. Similar tax deductions are being applied to conservation and maintenance expenses for landowners with contracts to keep part of their property as nature reserves. Costa Rica has introduced a fuel tax that is used to support the costs of managing protected areas. Ecuador provides cash incentives to support sustainable forest management by indigenous and local communities and landowners through its Socio-Bosque Programme. In both Ecuador and Costa Rica, a levy on city water supply helps to protect high-biodiversity water catchment areas.

Brazil provides an example of effective inter-ministerial action to protect biodiversity in its Action plan to protect and control deforestation in the Brazilian Amazon. The plan includes the establishment of protected areas and indigenous reserves, land planning using ecological and economic zoning, use of incentive schemes, monitoring by satellite and aircraft, and strengthened enforcement measures. The plan involves action by all relevant ministries including environment, agriculture, science and technology, justice and defence coordinated through an inter-ministerial working group under the authority of the President of the Federal Republic. Deforestation rates were reduced by some 80% in the period 2002–2012.

These examples demonstrate that success depends on a coherent approach across several ministries and levels of government, sectors of society and business.

Some national biodiversity strategies and action plans, especially the more recently developed or updated ones, encourage biodiversity planning at the subnational level, that is at the level of states or provinces and at the local, district, or municipal levels. This is relevant because many of the decisions affecting biodiversity, such as land-use planning decisions, are taken at local or other subnational levels. Moreover, in some countries, biodiversity planning at the subnational level is being promoted as part of broader programmes of decentralization or increased regional autonomy (e.g., China, Indonesia, Maldives, Myanmar, Pakistan). Some federal countries have promoted the development of state or provincial biodiversity strategies and action plans (e.g., India, which has 71 strategies and action plans including state strategies, local strategies, and eco-regional strategies; Mexico, where state biodiversity strategies have been adopted by Michoacán and Morales and are in preparation in another seven states). In addition, Peru has developed 17 “regional biodiversity strategies” as biodiversity planning instruments. Japan is promoting biodiversity strategies for its prefectures. The United Kingdom has a large number of local biodiversity action plans.

Many regions or subregions have developed regional biodiversity strategies or action plans: these include: the European Union Biodiversity Action Plan; the Central American Biodiversity Strategy (Central American Commission for Environment and Development (CCAD)); the Cooperative Strategy for the Conservation of Biological Diversity in the Arctic region (Conservation of Arctic Flora and Fauna); the Southern Africa Biodiversity Strategy (Southern Africa Development Community); the Andean Biodiversity Strategy (Andean Community); and the Regional Action Plan for Amazonian Biodiversity (Amazon Treaty Cooperation Organization). In addition, a number of regional mechanisms such as the Association of South-East Asian Nations and its Centre for Biodiversity, the European Union the CCAD, Commission of Forestry in Central Africa, Secretariat of the Pacific Regional Environment Programme, the Committee of Arab Ministers Responsible for the Environment of the League of Arab States, among others, play an important role in supporting implementation of the Convention.

With the adoption of the Strategic Plan for Biodiversity 2011–2020, most countries are updating their national biodiversity strategies and action plans, incorporating national targets in the framework of the Aichi Biodiversity Targets. For example, the new biodiversity strategy for England sets a target to establish and effectively manage an ecologically coherent network of marine protected areas which covers in excess of 25% of English waters by the end of 2016 (relating to Aichi Targets 6 and 11). Norway’s new biodiversity strategy includes a comprehensive set of targets for each of Norway’s six major biomes. Guatemala’s new strategy includes targets for reducing deforestation and for forest restoration. Colombia has developed a new biodiversity policy that focuses on maintaining and increasing ecosystem resilience. Brazil developed a comprehensive set of biodiversity targets in the framework of the 2010 global biodiversity target. This included a target to reduce the rate of deforestation in the Amazon biome by at least 75%, a target that was met, as noted above. Following a

series of dialogues among the various ministries of government and sectors of society, Brazil is developing an updated set of targets.

The CBD Regime: Supporting Action at the International Level

Advancing New Concepts

At the time of its inception, the CBD marked a departure from earlier international environmental law instruments by supporting a balance between conservation and sustainable use rather than promoting conservation only. It introduced novel legal concepts such as biodiversity, ecosystems, genetic resources and biotechnology, benefit sharing, and traditional knowledge. It provided an innovative and flexible framework for accommodating developed and developing countries’ concerns and capacities and for encouraging partnerships between national and local authorities, local and indigenous communities, and the private sector.

Over time, the Convention, through the SBSTTA and the Conference of the Parties has helped to translate a number of scientific concepts into politically recognized guidance. An example is the ecosystem approach. The ecosystem approach (Box 6) is a strategy for the integrated management of land,

Box 6 The 12 principles of the Ecosystem Approach

1. The objectives of management of land, water, and living resources are a matter of societal choices.
2. Management should be decentralized to the lowest appropriate level.
3. Ecosystem managers should consider the effects (actual or potential) of their activities on adjacent and other ecosystems.
4. Recognizing potential gains from management, there is usually a need to understand and manage the ecosystem in an economic context. Any such ecosystem-management program should:
 - a. Reduce those market distortions that adversely affect biological diversity;
 - b. Align incentives to promote biodiversity conservation and sustainable use;
 - c. Internalize costs and benefits in the given ecosystem to the extent feasible.
5. Conservation of ecosystem structure and functioning, in order to maintain ecosystem services, should be a priority target of the ecosystem approach.
6. Ecosystems must be managed within the limits of their functioning.
7. The ecosystem approach should be undertaken at the appropriate spatial and temporal scales.
8. Recognizing the varying temporal scales and lag-effects that characterize ecosystem processes, objectives for ecosystem management should be set for the long term.
9. Management must recognize the change is inevitable.
10. The ecosystem approach should seek the appropriate balance between, and integration of, conservation and use of biological diversity.
11. The ecosystem approach should consider all forms of relevant information, including scientific and indigenous and local knowledge, innovations and practices.
12. The ecosystem approach should involve all relevant sectors of society and scientific disciplines.

water, and living resources that promotes conservation and sustainable use in an equitable way. Application of the ecosystem approach helps to reach a balance of the three objectives of the Convention. It is based on the application of appropriate scientific methodologies focused on levels of biological organization which encompass the essential processes, functions, and interactions among organisms and their environment. It recognizes that humans, with their cultural diversity, are an integral component of ecosystems. The ecosystem approach requires adaptive management to deal with the complex and dynamic nature of ecosystems and the absence of complete knowledge or understanding of their functioning. As described by the Conference of the Parties, the ecosystem approach is the primary framework for action under the Convention. The Conference of the Parties, at its Fifth Meeting, endorsed the description of the ecosystem approach and operational guidance.

The Convention has also highlighted the linkages between biodiversity, ecosystem functioning, ecosystem services and human well-being, building on the work of the 2005 Millennium Ecosystem Assessment, and more recently on *The Economics of Ecosystems and Biodiversity (TEEB, 2010)*. Overall, these scientific and conceptual developments have helped to operationalize the ecosystem approach, albeit in an incomplete manner. They have also shed new light on the CBD's preambular language on biodiversity's importance for meeting the food, health, and other needs of the world's growing population and on biodiversity's social, economic, scientific, cultural, and other values. Conceptualising ecosystem services therefore highlighted the links between biodiversity and human development and, to that extent, "modernised" the concept of sustainable use (*Morgera and Tsoumani, 2011*).

Developing Guidance and Programs of Work

The CBD programs of work are the main instruments that CBD parties use to achieve the commitments contained in the Convention and the Strategic Plan for Biodiversity 2011–2020. They include guidelines for national implementation, often recommending reforms of national laws, policies, or administrative practices. The COP has established seven thematic work programs, namely on agricultural biodiversity, dry and subhumid lands biodiversity, forest biodiversity, inland waters biodiversity, island biodiversity, marine and coastal biodiversity, and mountain biodiversity; and five crosscutting work programs on incentive measures, the Global Taxonomy Initiative, protected areas, Article 8(j) (traditional knowledge), and technology transfer and cooperation.

Work has also been undertaken on a series of other crosscutting issues, including climate change and biodiversity, the ecosystem approach, and sustainable use of biodiversity. Some cross cutting initiatives directly support work under thematic programs, for example, the work on indicators provides information on the status and trends of biodiversity for all biomes. Others develop discrete products quite separate from the thematic programmes. The work done for these crosscutting issues has led to a number of principles, guidelines, and other tools to facilitate the implementation of the Convention (see [Box 7](#)).

In addition to the tools and guidance, the Conference of the Parties regularly establishes initiatives and undertakes assessment on developing biodiversity issues. For example, the Convention has ongoing work to examine the impacts on biodiversity of ocean acidification, biofuel production and use, and geoengineering. The findings or outputs from these processes are published as technical reports and provide a basis for policy guidance to Parties to avoid, reduce, or mitigate the impacts.

The work of the CBD on indigenous and local communities is founded on Article 8(j), which calls on parties to encourage the equitable sharing of the benefits arising from the utilization of the knowledge, innovations, and practices of indigenous and local communities embodying traditional lifestyles relevant for the conservation and sustainable use of biological diversity. The Convention's programme of work on Article 8(j) and related provisions has delivered not only guidelines but has also advanced the interests of indigenous people's in the Nagoya Protocol. In fact, the CBD has emerged as the preferred international forum for indigenous and local communities to express their interests and demands for the protection of their traditional knowledge, particularly within the CBD Working Group on Article 8(j), which affords community representatives broad participation rights (*Morgera and Tsoumani, 2011*).

Promoting Cooperation and Coherence Among International Instruments

The CBD was developed after a number of other biodiversity related agreements, namely the Convention on International Trade in Endangered Species of Wild Fauna and Flora, the Convention on the Conservation of Migratory Species of Wild Animals, the Ramsar Convention on Wetlands, and the World Heritage Convention. The CBD builds on these preexisting species-based and area-based international environmental agreements while establishing a wider context in which such agreements are interpreted and implemented. While the CBD is not formally an "umbrella" convention, because it does not supersede previous agreements, it has the normative character of an umbrella convention in articulating new norms that could also apply to preexisting agreements.

The CBD promotes close collaboration with and among these other international conventions that focus on biodiversity issues as well as the International Treaty on Plant Genetic Resources for Food and Agriculture. The governing bodies of each convention have set out specific mandates for cooperation among the biodiversity-related conventions, and a number of joint work programs have been established.

The Convention has also explored synergies with the other two Conventions born of the 1992 Rio Conference on Sustainable Development: the United Nations Framework Convention on Climate Change and the United Nations Convention to combat desertification. Building on assessments carried out by expert groups under the authority of SBSTTA, the Convention has developed policy guidance for ecosystem-based approaches to climate change mitigation and adaptation that can be used for linked implementation of national plans and strategies under the three Rio Conventions.

Box 7 Principles and Guidelines developed under the Convention

<i>Guidelines</i>	<i>Description</i>
Addis Ababa Principles and Guidelines for the Sustainable Use of Biodiversity	A framework for advising stakeholders on how they can ensure that their use of the components of biodiversity will not lead to long-term biodiversity declines, but will instead promote conservation and contribute to poverty alleviation. Applying to both consumptive and nonconsumptive uses of biodiversity, the Principles and Guidelines take into account issues related to policies, laws and regulations; management of biodiversity; socioeconomic conditions; and information, research and education.
Guiding Principles on Invasive Alien Species	The Guiding Principles are intended to assist governments to control invasive alien species, as an integral part of conservation and economic development. They comprise 15 principles on prevention, intentional and unintentional introduction, and mitigation of impacts.
Guidelines for Incorporating Biodiversity related Issues into Environmental Impact Assessment Legislation and/or Processes and in Strategic Environmental Assessment	Impact assessment is a comprehensive process and assessment tool that promotes sustainable development and is used to ensure that projects, programs and policies are economically viable, socially equitable, and environmentally sustainable. These guidelines provide advice on the incorporation of biodiversity-related concerns into new or existing environmental impact assessment (EIA) and strategic environmental assessment (SEA) procedures. Guidelines for EIA and SEA in marine areas, including the high seas, and areas beyond national jurisdiction are being developed under the Convention.
Akwé: Kon Voluntary Guidelines for the Conduct of Cultural, Environmental, and Social Impact Assessment regarding Developments on Lands and Waters Traditionally Occupied or Used by Indigenous and Local Communities	The guidelines provide advice on how to incorporate cultural, environmental (including biodiversity-related), and social considerations of indigenous and local communities into new or existing impact-assessment procedures, to ensure appropriate development. They support the full and effective participation of indigenous and local communities in screening, scoping and development planning exercises, taking into account their traditional knowledge, innovations and practices.
The Tkarihwaí:ri Code of Ethical Conduct to Ensure Respect for the Cultural and Intellectual Heritage of Indigenous and Local Communities	The guidelines contain ethical principles and propose methods for promoting respect for the cultural and intellectual heritage of indigenous and local communities relevant for the conservation and sustainable use of biological diversity.
Guidelines on Biodiversity and Tourism Development	A comprehensive instrument for managing tourism activities in an ecologically, economically and socially sustainable manner. The guidelines emphasize a consultative approach involving multiple stakeholders, and are structured around ten steps, from development of an overall vision to implementation of adaptive management programs.
Proposals for the Design and Implementation of Incentive Measures	Incentive measures serve to correct the failure of markets to properly reflect biodiversity's value to society. These Proposals identify and explain key elements that need to be considered when using incentive measures for the conservation and sustainable use of biodiversity. They also provide advice on the application of complementary measures for the provision of capacity-building, and for management, monitoring and enforcement.
Proposals for the Application of Ways and Means to Remove or Mitigate Perverse Incentives	Perverse incentives induce unsustainable behaviours that destroy biodiversity, often as unanticipated side effects of policies designed to attain other objectives. These Proposals offer a general framework for the removal or mitigation of perverse incentives, based on a three-phase approach: identification of policies and practices generating perverse incentives; design and implementation of appropriate reforms; and monitoring, enforcement and evaluation of these reforms.
Biodiversity and ecosystem-based approaches to climate change mitigation and adaptation	The Guidance provides ways to conserve, sustainably use and restore biodiversity and ecosystem services while contributing to climate change mitigation and adaptation, including: reducing the impacts on biodiversity of climate change, and of measures to address climate change.

The Convention has also developed guidance and promoted safeguards to ensure that mechanisms for reducing emissions of greenhouse gases from deforestation and forest degradation also help to protect biodiversity and the rights of indigenous and local communities (Reducing emissions from deforestation and forest degradation (REDD+)).

In cooperation with regional fisheries management organizations, the regional seas conventions and other international organizations, the Convention on Biodiversity is undertaking a process to describe ecologically and biologically sensitive marine areas. The results will be used by countries as well as by the United Nations General Assembly in their work

to establish marine protected areas or other means to protect these areas, including the high seas.

Actions to control and prevent the spread of invasive alien species, including pests of plants and animal diseases, are promoted through various national government departments which relate to various international agreements and organizations including the International Plant protection Convention, the World Organization for Animal Health and the International Maritime Organization as well as the World Trade Organization. A liaison group on invasive alien species brings together these and other organizations to promote cooperation in the development of international policy and standards and to support a coherent approach to implementation at the national level among border control officials, conservation officials, and others.

Strengthening Capacity and Providing Resources for Implementation

A number of processes have also been established as part of the CBD to help ensure that resources needed to carry out work in support of the Convention are available to countries. One of these is the Clearing House Mechanism (CHM). The term “clearing-house” originally referred to a financial establishment where checks and bills are exchanged among member banks so that only the net balances need to be settled in cash. Today, its meaning has been extended to include any agency that brings together seekers and providers of goods, services or information, thus matching demand with supply. In the case of the Convention the CHM serves as a means of sharing information among Parties and partners. In its next phase of work in order to contribute significantly to the implementation of the Strategic Plan for Biodiversity 2011–2020, additional effort will be required to promote technical and scientific cooperation including institutional cooperation and the exchange of expertise among Parties and partners. This will build on the successful work of national institutions such as Mexico’s Commission for the Conservation and Use of Biodiversity, Costa Rica’s Institute for Biodiversity, and the South African National Biodiversity Institute (SANBI).

The Convention provides for a financial mechanism, operated by the Global Environment Facility (GEF). To 2010, GEF has provided some \$3 billion in grants for biodiversity conservation and sustainable use and leveraged an additional \$8 billion in cofinancing for almost 1000 projects in 155 countries. For the period 2010–2014, the GEF is providing some \$300 m annually for biodiversity. About \$3 billion per year is provided in biodiversity-related bilateral aid representing less than 3% of overseas aid or development assistance. The largest sources of funding for biodiversity in developed and developing countries are domestic budgets; precise figures are not available but domestic support to biodiversity related activities globally is estimated to be of the order of \$100 billion per year. Virtually all countries report that financing for biodiversity is insufficient. To meet the ambitious Aichi Biodiversity targets, the Convention is developing its Strategy for Resource Mobilization. It is agreed that a substantial increase in financial resources from all sources will be required.

Challenges and Prospects for Achieving the Aichi Biodiversity Targets

The Strategic Plan for Biodiversity 2011–2020 with the Aichi Biodiversity Targets provides an ambitious plan for the international community to take urgent action to address biodiversity loss with a view to realizing a long term vision where, “by 2050, biodiversity is valued, conserved, restored and wisely used, maintaining ecosystem services, sustaining a healthy planet and delivering benefits essential for all people”. Some of the key challenges in achieving the targets and realizing this Vision are reviewed in this section.

Increasing Pressure for Land

Land-use change remains the biggest driver of biodiversity loss, at least in terrestrial ecosystems. The recent food crisis has thrown into sharp relief the increasingly strong multiple pressures for land: for crops and livestock to feed an expanding population and for meeting the increased consumption by that part of the population that can afford it; for biofuels which are supposed to contribute to the effort to mitigate climate change (but, in fact, frequently increase net emissions of greenhouse gases); and for infrastructure development, especially in the narrow band of 100 km from coastlines where the majority of the population lives and works.

Yet despite these pressures, there are some encouraging signs. One results from yet another demand for land use – for carbon storage and sequestration. Mechanisms such as REDD+ (the role of conservation, sustainable management of forests and enhancement of forest carbon stocks in developing countries) are being agreed and put in place to provide incentives for conserving forests and other ecosystems that contain high levels of carbon.

Perhaps more significant is the emerging consensus that biodiversity conservation and, specifically, reducing land conversion, is compatible with increased agricultural productivity. For example, a recent study looking at how agriculture can feed the world in a sustainable manner proposes four strategies that are consistent with the Strategic Plan for Biodiversity 2011–2020 (Foley *et al.*, 2011). These are: halting agricultural expansion; closing “yield gaps”; increasing the efficiency of use of water and nutrients; and shifting diets and reducing waste. Such strategies are consistent with Aichi Targets 5 (half deforestation and other loss of natural habitats), 7 (promote sustainable agriculture), 8 (reduce nutrient pollution) and 3 (sustainable consumption), respectively. Similarly, a study on the Future of Food and Farming commissioned by the United Kingdom Chief Government Science Advisor (Foresight, 2011) concludes that “there will hardly ever be a case to convert forests, especially tropical rainforests, to food production.” In fact, there is a range of technical and policy tools available to facilitate more rational and efficient land-use planning. Restoration of degraded land will also be increasingly be important – with so many demands for land use, leaving land in a degraded state will no longer be a viable option. A coalition of governments and international organizations is proposing to restore at least 150 million hectares of lost and degraded forests by 2020.

This is not to say that it will be easy to meet the multiple objectives of increasing food production, protecting biodiversity and sequestering carbon. The Foresight study calls for “nothing less ... than a redesign of the whole food system to bring sustainability to the fore”. Further Foley *et al.* acknowledge that “our analysis focuses on the agronomic and environmental aspects of these challenges, and leaves a richer discussion of associated social, economic, and cultural issues to future work”. Among these, the strengthening of rights to land and natural resources of indigenous and local communities will be a high priority.

Inadequate Protection of the Marine Environment

The largest threat to marine and coastal biodiversity has been overfishing and destructive fishing practices. These have resulted literally in the decimation – or more – of fish stocks and the transformation of marine habitats to less productive states, with severe losses on livelihoods and food security. Eutrophication and dead zones from land-based pollution and sedimentation are additional pressures. But in the marine realm too there are signs of progress (Worm, *et al.*, 2009). With well thought-out action, only a 10% reduction in fishing effort may be needed to half the pressure on marine ecosystems. Ending subsidies for fishing and especially for fuel would be a major step to sustainability. As noted above, by identifying ecologically and biologically significant marine areas, the Convention is paving the way for an expansion of marine protected areas in coastal waters and the high seas. Marine protected areas would also help to maintain or increase the resilience of marine ecosystems to global warming and ocean acidification.

The Increasing Threat of Climate Change

Climate change imposes an increasing severe range of threats to biodiversity and ecosystem services, greatly increasing the risk of species extinctions and local losses. Urgent and large-scale action to reduce emissions from fossil fuels and land-use change is needed. Reducing this threat to biodiversity requires progress under the sister Convention – the United Nations Framework Convention on Climate Change (UNFCCC). The Cancun (2010) and Durban (2011) agreements under the UNFCCC are steps forward. However, as noted above (*see* Developing Guidance and Programs of Work), action under the CBD can contribute to climate change mitigation and adaptation. Relevant actions include minimizing other pressures on biodiversity (as articulated in Aichi Target 10), protecting genetic diversity to allow adaptation to future conditions (Aichi target 8), and restoring ecosystems, thereby contributing to both adaptation (though increased ecosystem resilience) and mitigation (though carbon sequestration) (Aichi Target 15).

The Unachieved Goal of a Sustainable Economy

Ultimately achieving the goals of the CBD as well as those of the Climate Convention, will require a genuine shift to sustainable production and consumption patterns. A full discussion of the measures needed in this regard is beyond the

scope of this article. However changes in public perception and behaviour (see Aichi Target 1), inclusive wealth accounting (including integration of biodiversity into national accounts as called for in Aichi Target 2), and subsidy reform (Aichi Target 3) are key elements. Changes in consumption patterns are also key (Aichi Target 4). Some changes such as moderation in meat consumption would deliver real health benefits for people and the planet.

The Need for Concerted Action

A study commissioned by the Executive Director of the United Nations Environment Programme (Netherlands Environment Assessment Agency, 2010) for the international year of biodiversity showed that while it would not be possible, given other socioeconomic imperatives, to halt biodiversity loss in the next few decades, even less by 2020, an aggressive implementation of a combination of measures to expand protected areas, reduce deforestation, improve forest management, reduce fishing efforts, increase agricultural efficiency by closing the yield gap, reduce food waste, change diets and mitigate climate change could halve the loss of biodiversity (using mean species abundance as indicator) by 2030. With the addition of aggressive plans for ecosystem restoration, somewhat more ambitious goals may be justifiable (ten Brink, personal communication). Like the other studies referred to above (*see* Increasing Pressure for Land), this reinforces the general messages provided in Global Biodiversity Outlook Reports and broadly support the feasibility of the Strategic Plan for Biodiversity 2011–2020.

As acknowledged in a number of studies, this is a unique time in history – Humanity is now the major force altering the planetary environment and decisions made now and over the next few decades will disproportionately affect the future.

Glossary

Formal education Education that takes place in a school environment.

Informal education Education that takes place in nonschool settings, such as museums, zoos, parks, or through the media.

Out of school experiences Things that individuals experience that may support or reinforce learning. These

might include participation in youth-serving organizations or hobbies such as bird watching.

Science literate Referring to a person who has fundamental knowledge and understanding of, as well as comfort with, the concepts, ideas, and nature of science.

Systematics Area of biology related to the classification of living things based on their relationships and evolutionary history.

Introduction

The Convention on Biological Diversity articulates a case for nations of the world to come together to undertake activities to improve conservation of biodiversity and sustainable use of biological resources. As of November 2010 more than 190 nations had ratified the convention and 170 had developed national biodiversity strategies and action plans. In addition to calls for better management, more research and study, protection of traditional knowledge, and international and regional cooperation, there was also recognition of the role of education, public participation, public information, and the development of a cadre of professionals to support the goals of the convention.

A 1998 report to President Clinton from the President's Committee of Advisors on Science and Technology (PCAST) makes recommendations to strengthen "the understanding and management of biological resources" (PCAST, 1998). Among the recommendations in *Teaming with Life: Investing in Science to Understand and Use America's Living Capital*, are calls for increased opportunities for formal and informal education centered on biodiversity and ecosystems, for interactions between scientists and students, and for continuing professional education for K–12 teachers.

Biodiversity: Connecting with the Tapestry of Life (Alonso *et al.*, 2001), prepared by the Smithsonian Institution's Program on Monitoring and Assessment of Biodiversity, under the Conservation and Research Center of the National Zoological Park and President Clinton's PCAST, sounded a similar theme as to the importance of biodiversity and the role of education and public awareness in its protection.

This article will outline aspects of formal and informal education focused on biodiversity. Specifically, it will outline learning goals around biodiversity for K–12 education, recommended school-based experiences that can lead to an attainment of these goals, and evidence as to the extent to which these understandings are being achieved by students. The article will review school-based environmental education initiatives and describe how these compare to and differ from education about biodiversity. The article will then continue with a discussion of informal learning opportunities in "places of science" as well as those available through youth-serving organizations, tourism, and field experiences. The section on

general education will conclude with information on public interest in and awareness of biodiversity.

A brief section will discuss biodiversity and tertiary education: Biodiversity themes and courses as part of liberal education as well as issues in the education of professionals and specialists who work in biodiversity research, management, and conservation.

Learning About Biodiversity: K–12 Education

How do students learn about biodiversity? What specific concepts must they learn and what ideas must they acquire to support that understanding? What class work, materials, curriculum, set of courses, and experiences would provide an adequate background so that they come to an understanding of this concept?

In 1985 the American Association for the Advancement of Science (AAAS) began Project 2061, a long-term initiative to reform K–12 education in natural and social sciences, mathematics, and technology. *Science for All Americans*, (Project 2061, American Association for the Advancement of Science, 1989) was conceived as a statement of learning goals for science, mathematics, and technology education, defining what all students should know and be able to do by the time they conclude secondary education. *Science for All Americans* includes learning goals related to biodiversity (see **Box 1**). *Benchmarks for Science Literacy* (*Benchmarks* (Project 2061, American Association for the Advancement of Science, 1993)) and the *National Science Education Standards* (*Standards*), published by the **National Research Council** in 1996, describe the ideas that students must grasp at different ages (grades or developmental levels) in order to understand science concepts, including the overall concept of biodiversity.

Grades K–2

For young children in early primary education, *Benchmarks* recommends that students learn the following:

- Some animals and plants are alike in the way they look and in the things they do, and others are very different from one another.

Box 1 Biodiversity: What would a science literate adult understand?**Diversity of Life**

Millions of different types of individual organisms inhabit the earth at any one time — some very similar to each other, some very different. Biologists classify organisms into a hierarchy of groups and subgroups on the basis of similarities and differences in their structure and behavior. One of the most general distinctions among organisms is between plants, which get their energy directly from sunlight, and animals, which consume the energy-rich foods initially synthesized by plants. But not all organisms are clearly one or the other. For example, there are single-celled organisms without organized nuclei (bacteria) that are classified as a distinct group.

Animals and plants have a great variety of body plans, with different overall structures and arrangements of internal parts to perform the basic operations of making or finding food, deriving energy and materials from it, synthesizing new materials, and reproducing. When scientists classify organisms, they consider details of anatomy to be more relevant than behavior or general appearance. For example, because of such features as milk-producing glands and brain structure, whales and bats are classified as being more nearly alike than are whales and fish or bats and birds. At different degrees of relatedness, dogs are classified with fish as having backbones, with cows as having hair, and with cats as being meat eaters.

For sexually reproducing organisms, a species comprises all organisms that can mate with one another to produce fertile offspring. The definition of species is not precise, however; at the boundaries it may be difficult to decide on the exact classification of a particular organism. Indeed, classification systems are not part of nature. Rather, they are frameworks created by biologists for describing the vast diversity of organisms, suggesting relationships among living things, and framing research questions.

The variety of the earth's life forms is apparent not only from the study of anatomical and behavioral similarities and differences among organisms but also from the study of similarities and differences among their molecules. The most complex molecules built up in living organisms are chains of smaller molecules. The various kinds of small molecules are much the same in all life forms, but the specific sequences of components that make up the very complex molecules are characteristic of a given species. For example, DNA molecules are long chains linking just four kinds of smaller molecules, whose precise sequence encodes genetic information. The closeness or remoteness of the relationship between organisms can be inferred from the extent to which their DNA sequences are similar. The relatedness of organisms inferred from similarity in their molecular structure closely matches the classification based on anatomical similarities.

The preservation of a diversity of species is important to human beings. We depend on two food webs to obtain the energy and materials necessary for life. One starts with microscopic ocean plants and seaweed and includes animals that feed on them and animals that feed on those animals. The other one begins with land plants and includes animals that feed on them, and so forth. The elaborate interdependencies among species stabilize these food webs. Minor disruptions in a particular location tend to lead to changes that eventually restore the system. But large disturbances of living populations or their environments may result in irreversible changes in the food webs. Maintaining diversity increases the likelihood that some varieties will have characteristics suitable to survival under changed conditions. As noted in *Science for All Americans*, Project 2061, from the American Association for the Advancement of Science: PCAST, 1998.

- Plants and animals have features that help them live in different environments.
- Stories sometimes give plants and animals attributes they really do not have.

Recommended learning activities include providing students with the opportunity to observe a variety of plants and animals in the classroom; on the school grounds; in the community; at home in parks, streams, and gardens; and at the zoo. The observations will prompt students to pursue questions about how the organisms live, where they are found, or how they interact with other organisms.

Grades 3–5

For children in later primary education, *Benchmarks* recommends that students learn the following:

- A great variety of kinds of living things can be sorted into groups in many ways using various features to decide which things belong to which group.
- Features used for grouping depend on the purpose of the grouping.

Recommended learning activities include providing students with the opportunity to learn about an increasing variety of living organisms and offering them a chance to invent schemes for classification. Students would be encouraged to develop different classification schemes (without being introduced to the Linnean classification system) and shown how their usefulness varies depending on the purpose of the

classification. The purpose of the work would be to help students develop a deeper understanding about the relatedness of organisms.

Grades 6–8

For children in upper primary and lower secondary education *Benchmarks* argues that science should provide students with opportunities to enrich their growing knowledge of the diversity of life on the planet and to begin to connect that knowledge to what they are learning in geography. That is, whenever students study a particular region in the world, they should learn about the plants and animals found there and how they are like or unlike those found elsewhere.

Food patterns of development, and external and internal structures, would all be used to illustrate interrelationships, interdependence, similarities, and differences. Students would be introduced to the features that biologists use in classification systems and would be taught why these classifications are made.

Benchmarks suggests that students in this group should know the following:

- One of the most general distinctions among organisms is between plants, which use sunlight to make their own food, and animals, which consume energy-rich foods. Some kinds of organisms, many of them microscopic, cannot be neatly classified as either plants or animals.
- Animals and plants have a great variety of body plans and internal structures that contribute to their being able to make or find food and reproduce.

- Similarities among organisms are found in internal anatomical features, which can be used to infer the degree of relatedness among organisms. In classifying organisms, biologists consider details of internal and external structures to be more important than behavior or general appearance.
- For sexually reproducing organisms, a species comprises all organisms that can mate with one another to produce fertile offspring.
- All organisms, including the human species, are part of and depend on two main interconnected global food webs. One includes microscopic ocean plants, the animals that feed on them, and finally the animals that feed on those animals. The other web includes land plants, the animals that feed on them, and so forth. The cycles continue indefinitely because organisms decompose after death to return food material to the environment.

Grades 9–12

For students at the secondary level, curricular objectives lead to understanding diversity within and among species by looking at same and different features at a molecular level. Students would learn the following:

- The variation of organisms within a species increases the likelihood that at least some members of the species will survive under changed environmental conditions, and a great diversity of species increases the chance that at least some living things will survive in the face of large changes in the environment.
- The degrees of kinship between organisms or species can be estimated from the similarity of their DNA sequences, which often closely matches their classification based on anatomical similarities. Understanding built up over this period of study would lead students to comprehend the diversity of ecosystems, diversity of species, and the genetic diversity within species.

While *Benchmarks* sets out a recommended sequence of learning goals to help students come to an understanding of biodiversity as a complex idea, it is not clear that most students have access to the education, ideas, concepts, and learning experiences needed to achieve such understandings. Therefore it would be necessary to explore what students are taught or expected to learn over time during their schooling.

Biodiversity and School Science

Formal education in science is an important contributor to students' fundamental understandings about science. While self-directed study – books, articles, the Internet, museum visits, and field experiences – augment science learning for many students, the quality of the curriculum, textbooks, and other instructional materials, the preparation of teachers, the school-mediated experiences provided to students both inside and outside of the classroom all interact to shape what students take away from school science. Understandings of biodiversity would be based on accumulated experiences and knowledge. These would include the early school focus on

natural history and nature study and development of an intuitive understanding of biological diversity and the relationships among living organisms (National Research Council, 1990). Students' out-of-school experiences, where such are available, would reinforce school learning. The curriculum focus shifts in lower and upper secondary levels (grades 6–12) to more formal, taxonomic instruction.

This pattern of topic coverage for life sciences concepts is present in the curriculum of other countries around the world and was prevalent among the majority of the 50 countries that participated in the Trends in International Mathematics and Science Study (TIMSS). Data were collected in 2007 and results presented in 2008. In addition, the 2011 framework for the upcoming assessment contains similar topical coverage of life sciences concepts; over 60 countries are slated to participate.

In the US, according to statistics provided by the U.S. Department of Education (2007), biology is the most frequently taken high school science course, with over 92% of 2005 graduates of public and private high schools reporting having completed such a class. Analysis of content core is not available to determine the extent to which the ideas critical to a student's understanding of biodiversity are actually taught. It is also not clear if earlier foundational ideas are provided to students as a part of instruction at primary and lower secondary levels. One trend that has emerged since the late 1990s is the increase in the percentage of students taking Advanced Placement/Honors biology courses *in lieu* of so-called general biology.

In the US there has been considerable discussion about the adequacy, pacing, and structure of curriculum and, especially, of textbooks in middle and high school biology. Researchers have criticized their encyclopedic nature, with too many ideas covered too superficially, and too much focus on vocabulary at the expense of big ideas. In addition, there has been a movement to avoid instruction of controversial topics such as evolution, a central idea in biodiversity. A 1999 study that evaluated the science textbooks used in middle grades against three concepts from *Benchmarks* and *Standards*, one each from the earth, physical, and life sciences, led the AAAS Project 2061 to conclude that all nine titles examined were inadequate to help students achieve understanding of the ideas that they were attempting to explain.

Efforts to actually measure what students know about science are undertaken through the regularly administered National Assessment of Educational Progress and recently have been internationally benchmarked through TIMSS. At lower and upper secondary levels, the results suggest that US students gain little real understanding of the big ideas of science, including life sciences, in spite of the fact that they are most likely to have had formal classes in this area than in other areas of science. It has largely been in the study of biology that the basic concepts of biodiversity have been advanced; diversity within species, across species and ecosystems; relatedness of species; interdependence among living things; threats to this diversity due to population pressures; loss of habitat; changes in species over time; natural extinctions; and human induced extinctions. While biodiversity and biodiversity education are more recent concepts, nature study, conservation, and environmental education have older roots, in a more

general emphasis on environmental improvement and appreciation. The following section will explore some of the history of environmental education and consider how it might relate to biodiversity education.

Environmental Education

In 1977 the world's first intergovernmental conference on environmental education was organized by the United Nations Education, Science, and Cultural Organization (UNESCO) in cooperation with the United Nations Environment Programme and held in Tbilisi, Georgia (Soviet Union). The Tbilisi Declaration, adopted at the conference, stressed the importance of environmental education in the preservation and improvement of the world's environment. Agenda 21, Chapter 36, outlines issues related to formal education, public awareness, and training to promote sustainable development and emphasizes environmental and development education as an essential aspect of all education. There were also calls for linking to environmental education in recommendations from the World Conference on Education for All (held in Jomtien, Thailand in 1990) that urged a move toward universal access to basic education for girls and boys.

The recommendations include calls for better informal education, promotion of environmentally sound leisure and tourism activities, programs to involve young people and children, as well as respect for and support of efforts to promote dissemination of traditional and socially learned knowledge through mechanisms based in local cultures.

Environmental education was called "nature study" when it got its start in the 1920s with Junior Audubon Clubs teaching children to appreciate nature. According to Karen Schmidt in a December 13, 1996, article in *Science*, the movement was transformed into conservation education in the 1930s when the Dust Bowl environmental tragedy led to incorporation of ideas into some schools about the management of natural resources.

With the initiation of Earth Day in 1970 and passage of the National Environmental Education Act of 1970, teachers

received supplemental training in environmental education. Many states enacted their own environmental education laws, and schools began incorporating these topics into science classes. On the 20th anniversary of Earth Day, President Bush signed the National Environmental Education Act of 1990, which created an Office of Environmental Education at the Environmental Protection Agency and supported curriculum development and teacher training in the states.

In the US concern has been expressed about the place of environmental education, as currently configured into the curriculum, and especially about the quality of programs sometimes offered in lower secondary schools. This has included concerns about an advocacy orientation in instruction, about the need for and balance in materials used and instruction provided. The North American Association for Environmental Education (NAAEE), a professional group that includes college faculty and K-12 educators among its members, developed Guidelines for Excellence (North American Association for Environmental Education, 2004) to help guide teachers and others in the selection of quality, balanced materials. NAAEE membership includes individuals throughout North America as well as in 55 countries around the world.

Teaming with Life made a strong recommendation that environmental education should have a stronger base in science, using scientifically grounded curricula. Innovative programs such as Global Learning and Observation to Benefit the Environment (GLOBE) (see [Box 2](#)) that depend on student-scientist partnerships and collection of real data may point the way to science education based around environmental and biodiversity concerns.

Learning in the Informal Education Sector

Overview

A wide range of informal education experiences are available for adults and children to extend their knowledge about biodiversity. These include organizations that incorporate biodiversity education and exhibition within their missions, such

Box 2 Global Learning and Observation to Benefit the Environment (GLOBE)

GLOBE, a hands-on, school-based international environmental science program, was introduced by US Vice President Al Gore in April 1994 and began operation on Earth Day in April 1995. In 1999 there were more than 6000 participating schools in more than 70 countries. GLOBE brings together students, teachers, and scientists from around the world to enhance environmental awareness of individuals worldwide, increase scientific understanding of the earth, and support improved student achievement in science and mathematics.

Students make environmental observations, or take environmental measurements near their school site, report their observations *via* the Internet, receive and use GLOBE images created from the combined data, and study the environment by relating their observations to larger environmental topics. GLOBE educational materials were developed by environmental educators and curriculum development specialists working with scientists. Materials are used in schools under the guidance of teachers who have received training using GLOBE materials. Teachers include GLOBE activities as appropriate within their local curriculum. GLOBE materials are translated into the six United Nations' languages (Arabic, Chinese, English, French, Russian, and Spanish) and are also available in over 45 other languages. GLOBE international partners sign bilateral agreements with the US and manage participation of schools in their countries. In the US, GLOBE is an interagency program with management infrastructure funded by the National Oceanic and Atmospheric Administration, the National Aeronautics and Space Administration (NASA), and the National Science Foundation, supported by, the U.S. Department of State and implemented through a cooperative agreement between NASA and the University Corporation for Atmospheric Research. In 2010 there were 111 participating countries, 54 000 GLOBE-trained teachers, and 23 000 schools in the program. Over 1.5 million students have participated, taking over 21 million measurements.

Observations range from basic weather parameters (temperature, atmospheric pressure, and precipitation) to measurements such as water chemistry, biodiversity, and biomass assessment. The focus to date has been more heavily directed toward physical systems measurements. Potential is great to increase the biodiversity and life systems aspects of the project.

as the following: Zoos; Botanical gardens; Aquariums; Museums; and National parks.

Depending on their size, these places of science might also incorporate research, collections, conservation, or other functions important to biodiversity. Signage and docent-led and audio tours provide additional information to visitors. Classes, lectures, and workshops (including those for teachers) are also often provided to extend the learning experience. Increasingly, materials and web sites incorporate aspects of a visit, bringing resources to audiences at a distance to make some part of the visitor experience remotely available.

Informal education also includes more intensive immersion experiences such as where it is incorporated into visits to natural preserves such as parks (including those within national park systems) and forests, or that provided through ecotourism.

Interpretive programs using volunteers, staff, and written and video materials provide enhanced learning experiences by bringing the science, the issues, and the concerns into sharp focus as a part of the overall environmental experience. Programs such as Earthwatch have biodiversity-focused visits that involve the participant in the research as data collector. Other informal learning opportunities are available through television and IMAX programs, web sites, and books.

Youth-serving groups provide a broad range of activities and experiences that can support education around concepts of biodiversity (see [Box 3](#)). Many may involve long-term projects of environmental monitoring, animal and plant breeding, habitat restoration, and other activities undertaken individually or in groups.

Exciting new online resources have been developed that serve both the formal and informal education communities around biodiversity education.

Zoos and Other Places of Science

Animal parks were established by and for rulers. Maier and Page, in their volume *Zoo: The Modern Ark* (Maier *et al.*, 1990), describe how animals were kept by royalty for entertainment and as a show of wealth. The third dynasty ruler of the Sumerian city of Ur had a park that dated around 2300 BC. A millennium later as civilization spread in the Near East and Asia, rulers and pharaohs exchanged “exotic” animals for their zoos. Emperor Wu Wang of the Chou dynasty laid out a zoological garden called the Park of Intelligence. Animal collections were found around the globe in early civilizations such as in Egypt some 3500 years ago.

Alexander the Great, perhaps influenced by Aristotle’s private menagerie, installed what was perhaps the first public zoo in Alexandria, Egypt.

With the coming of the Dark Ages of Europe, monasteries became the keepers of menageries and game parks. When Cortes arrived in the Aztec capital of Tenochtitlan, he found a large zoo behind Emperor Montezuma’s palace. Zoos in India were established by Akbar toward the end of the 16th century. He, like the Aztecs, employed people specially trained to care for and medically tend to animals.

The zoo at Vienna was reinvigorated by Maria Theresa and her husband as the Imperial Menagerie at Schönbrunn for the

Box 3 Selected youth serving groups providing informal science/environmental education

American Camping Association (ACA)

Founded in 1910

ACA provides an accrediting mechanism for camps. Of the more than 2400 accredited camps listed, 284 provided nature/environmental study as part of the camp experience.

Boy Scouts of America (BSA)

Enrollment: 5.6 million

Program: Incorporated in 1910 BSA provides programs for boys that include outdoor skills, nature study, and conservation activities through an elaborated badge structure and group activities. BSA is a charter member of the World Scout Conference.

World Scout Conference includes 145 member associations representing more than 25 million scouts.

Boys and Girls Clubs of America

Enrollment: 3 million youth; served in 1006 local organizations

Program: Activities include outdoor and environment education (The Ultimate Journey).

Camp Fire Boys and Girls

Enrollment: 750,000 young people (birth–age 21)

Program: Camping and environmental education programs offering children an appreciation and commitment to the natural environment.

Girl Scouts of the USA (GSUSA)

Enrollment: 3.5 million

Program: Activities include out-of-doors, nature study. Badge structure that includes environmental issues. GSUSA is a member of the World Association of Girl Guides and Girl Scouts.

World Association of Girl Guides and Girl Scouts undertakes world projects including building world citizenship. Environment is one of the themes of this program.

Girls Incorporated

Enrollment: 900,000 girls (ages 6–18) at more than 1000 sites nationwide

Program: Activities include experiences in mathematics and science education through Operation SMART

National 4-H Clubs

Enrollment: 6.5 million in more than 90,000 clubs

Program: Part of the U.S. Department of Agriculture’s Cooperative Extension Service established in 1914. Project areas include agricultural and natural sciences, and technology; Cornell Nest Box network.

convenience and entertainment of the nobility. The zoo remains today as likely the oldest in continuous operation, dating from the 1750s.

Democratization of Europe and establishment of urban centers that accompanied industrialization led to the modern zoo as a repository of exotic specimens of life that were to be studied as a way of understanding the flora and fauna of the world. Public monies (rather than private patrons or royal largesse) were available to begin systematic scholarly study. Maier and Page date the modern zoo to 1826 when the Zoological Society of London founded the zoological gardens at Regent's Park for the purpose of understanding the natural history of the animals inhabiting the reaches of the British Empire.

Since zoos as public institutions had to raise funds and attract money (independent of their research and conservation goals), they had to become popular attractions. Zoo organizers also had to learn to manage space and figure out and meet animals' requirements, such as for social interaction. Zoos' role in conservation became educational as they raised visitor awareness about endangered species and loss of habitat. Where larger zoos also developed significant breeding herds, they established breeding farms. In San Diego, for example, this "wild animal park" has become an additional attraction.

The National Zoological Park (National Zoo), associated with the Smithsonian Institution, established a "biopark," Amazonia, to emphasize the relationships among soil, plant, invertebrate, and other animal forms and the need to preserve the habitats of the world. Zoos, aquariums, and game parks are being seen as tools to affect public attitudes regarding the variety of life on earth.

As these places of science intentionally blend education and entertainment they are increasingly adding materials from museum collections and incorporating interactive exhibits from science-technology centers to reinforce conservation messages, concern about loss of species numbers and diversity, and loss of habitat.

Botanical Gardens

According to BGCI, the global network devoted to the conservation of threatened plant species, more than 200 million persons visited botanical gardens around the world. In addition to visits and guided tours, gardens offered continuing education for adults, workshops and hands-on experiences for children and families, and professional education courses and seminars for K-12 teachers. The New York Botanical Garden and Missouri Botanical Garden are examples of two gardens offering graduate studies programs, usually in collaboration with universities in their area.

Museums

Through collections, education programs, exhibitions, and graduate-level research, museums have been very active in promoting biodiversity in both the formal and informal sectors. The American Museum of Natural History in New York (AMNH) provides an interesting example of an institution with current involvement in all these areas:

- **Exhibition.** The 11,000-square-foot Hall of Biodiversity is a permanent exhibit of AMNH which opened in 1998. The exhibit uses collections, interactive technologies, and an immersive environmental replica of a portion of the rain forest of the Central African Republic – complete with sound, smell, movement, and running water – to provide a unique visitor experience.
- **Graduate and continuing education.** The Center for Biodiversity and Conservation collaborates within and outside the museum in the development of courses and programs. AMNH is home to the oldest and largest doctoral and postdoctoral training program of any scientific museum in the world, collaborating with Yale, Columbia, Cornell, and City University of New York.
- **Education.** The National Center for Science Literacy, Education and Technology, supported by the National Aeronautics and Space Administration (NASA) and a number of private foundations, has developed a number of projects related to the theme of biodiversity, including *Biodiversity Counts: A Student Inventory Project*, a program for middle school students across the US to inventory plant and animal life in their communities and to share their findings through publications and on-line field journals.

Biodiversity Experiences and Resources

Overview

For most adults, biodiversity education will take place in the informal sector as they read books; visit zoos, museums, and national parks; listen to lectures; and watch programs on the increasing number of science- and nature-based cable channels, public television, or the increased coverage of science on the news or news magazines. Others will visit the World Wide Web, where an increasing number of excellent sites developed by universities, museums, federal agencies, and nonprofit organizations provide high-quality information. Several examples of resources for biodiversity education available to the adult public follow.

Earthwatch

Earthwatch Institute is an international nonprofit organization founded in 1971 that supports scientific field research worldwide. Volunteers participate in actual field research, assisting scientists in gathering data. Since its beginning it has deployed over 85,000 volunteers into the field to work with 1000 scientists. Since 1995 Earthwatch's Capacity Development Program has trained over 1000 scientists including around species identification and other conservation issues. The Earthwatch web site lists active projects that volunteers can join in a number of topical areas including endangered species.

National Biological Information Infrastructure (NBII)

The NBII attempts to organize the disparate sources of information available through agencies, departments, museums, and other organizations, providing a source of links to sites. A "Biodiversity, Systematics and Collections" section connects to other web sites, many of which have education or "for kids" sections. Many federal agencies such as the U.S. Geological

Survey, the Environmental Protection Agency, NASA, and others have relevant sites.

Nonprofit Environmental and Biodiversity Groups

A number of organizations produce materials to support education about environmental and biodiversity issues. These include groups such as the World Wildlife Fund, the Sierra Club, and the Audubon Society. These groups develop a wide variety of public information and educational materials.

While most mainstream advocacy groups are conscious of the need to “get the science right” and to present balanced viewpoints, concerns are sometimes expressed about school use of materials that emanate from an advocacy position. Guidelines have been developed by NAAEE to assist educators in assessing the scientific accuracy of such materials.

Online Resources

Resources available online have added a new dimension to biodiversity education, most notably the Encyclopedia of Life (EOL). Initiated as a vision of biologist E.O. Wilson and funded by the MacArthur and Alfred P. Sloan Foundations, EOL is a free online collaborative reference tool that proposes to document every one of the 1.9 million known living species. As so-called Cornerstone Institutions, it brings together the resources of several of the world’s leading natural history museums, botanical gardens, and libraries. The encyclopedia will continue to grow as more global partnerships are developed. The EOL went live on 27 February 2008 with 30,000 entries.

Available to support biological science educators, BiosciEdNet (BEN) is a collaboration of biological science organizations and other groups, managed by the AAAS, that aim to provide quality bioscience materials to support teaching and learning. Nearly 1688 reviewed materials covering 77 topics are aggregated under this portal, including almost 800 teaching resources for biodiversity. BEN is one of the National Science Digital Library sites supported by the National Science Foundation.

Public Awareness

How much does the public understand about environmental issues in general and biodiversity in particular, and what are the attitudes toward these issues? Surveys from a number of sources indicate that there is strong public interest in and support for issues related to the environment. The *National Science Board’s Science and Engineering Indicators* (2010) suggested strong interest and “informedness” of the public around environment and health topics, especially when compared with other science and technology areas. The 1997 National Environmental Report card, an attitudinal and knowledge survey of American adults conducted by the National Environmental Education and Training Foundation and Roper Starch Worldwide, concluded that there was “an alarming lack of knowledge about some of our most critical environmental problems.” With regard to biodiversity, however, 73% of adults surveyed correctly responded about the

direct relationship between species loss and habitat destruction. The 1996 Biodiversity Poll (Belden & Russonello and Roper Starch Worldwide, 1997, 1998, 1999), conducted by the public opinion research firms Belden & Russonello and R/S/M, revealed the following about the environment and biodiversity:

- People care about the environment, but it isn’t in the top tier of public concerns.
- Of environmental concerns, the public considers the most serious problems to be toxic waste, destruction of the rain forest, loss of places in nature, and air and water quality.
- Extinction is a concern, but it is not high on the list.
- People understand that nature is connected and interdependent, but most people do not recognize or use the word biodiversity. Only two in 10 said they had heard about the “loss of biological diversity.”
- The public understands that species are declining and that human activity is largely responsible. But the public does not understand much about specific reasons or about the seriousness of the rate of loss.
- Public support for biodiversity conservation (once biodiversity is explained) is wide – 87%. But this support is shallow.
- Countervailing pressures (values) can peel support away from biodiversity protection. These include concerns about jobs, individual property rights, comfort and convenience, and preservation of unattractive species. However, 51% of Americans agree that the world would suffer if such unattractive species (e.g., mosquitoes) are eliminated.

The reasons Americans think biodiversity should be conserved included personal and family issues (79%), responsibility to future generations (71%), and spiritual concerns of stewardship (67%) (i.e., Nature is God’s work).

Another survey of biological scientists, science educators, and the general public conducted by the American Museum of Natural History in April 1998 revealed that most scientists believe we are in the middle of a mass extinction largely caused by human activity (American Museum of Natural History, 1998). While 70% of the scientists surveyed rated loss of biodiversity as major and urgent, the general public was generally unaware of species loss and the threats this posed. Even science teachers, who are aware of the biodiversity crisis, did not believe that there was mass extinction, and only 38% of teachers rated themselves as being very familiar with the concept of biodiversity. Both 1996 and 1998 polls revealed a large gap between scientists’ perception and the public’s awareness and concern about biodiversity, this in spite of the public’s perceived attentiveness and informedness about environmental issues in general.

The gap may relate to the following:

- A general lack of attention to biodiversity and its consequences by the media.
- The way that the public message about biodiversity is conveyed.
- The biological understandings that members of the public bring to the discussion.

Interestingly, the spottiness of adult knowledge and concepts (some individual ideas understood, but not the overall

concepts nor the consequences that flow from them) tracks with observations made about the K–12 student understanding of life sciences ideas. For most members of the public, high school is the last time for a formal course in the life sciences. After that, they generally rely on the informal sector for additional information and updates to their knowledge.

The 1999 National Environmental Report Card revealed that 84% of Americans believe that loss of animal and plant species is very serious or somewhat serious. Despite this support, however, specific concern for biodiversity within the larger frame of environmental issues appeared to have declined over the ensuing decade, as concerns for air and water quality have grown.

The United Nations declared 2010 as the International Year of Biodiversity; and later declared 2011–2020 as the United Nations Decade on Biodiversity. Such enhanced visibility will likely increase the number of events and level of attention directed to the public over this period of time.

Colleges and Universities

According to *Science and Engineering Indicators*, persons taking college-level science courses are more likely to be informed about, supportive of, and interested in science and technology topics. College level courses in biology influence knowledge and attitudes of the public. *Beyond Biology 101*, produced by the Howard Hughes Medical Institute, describes efforts to transform college-level courses in biology for both majors and nonmajors, moving away from vocabulary-driven courses to ones that are more integrative and that include meaningful laboratory and field experiences. These include an innovative program in human biology developed and in place since the 1960s at Stanford University. The program, taught by faculty from biology, education, anthropology, psychology, and other disciplines, focuses on the relationship between human biology and human behavior including human interactions with environment. It is a major course of interdisciplinary study and provides introductions to integrative biology for nonmajors.

The program for majors involves students in a range of activities designed to get them to think like scientists. Biodiversity and human impacts on the environment are explicit foci of instruction, and in the late 1980s and 1990s the college program was translated into a middle grades life sciences project (HumBio). Biodiversity concepts and activities are explicitly included among the curriculum materials in the ecology theme.

While most four-year institutions offer majors in biology or related subspecialties (including ecology), biodiversity was found as an area of major concentration at only a few US colleges and universities. A 2011 report published by the American Association for the Advancement of Science, *Vision and Change in Undergraduate Biology Education: A Call to Action*, summarized the consensus of conversations and discussions of life sciences educators as to what constitutes critical themes and competencies for introductory courses in biology; important among these was evolution as the driver for the diversity of life.

A search of the Society of Conservation Biology site, led to the international directory of conservation programs which lists 519 schools and 588 academic programs. Some 47 countries are listed in the directory as having academic programs.

The United Nations University, Institute for Natural Resources in Africa (UNU/INRA) was established in 1986 to “support the building of African capacity by strengthening national institutions to promote sustainable use of the continent’s natural resources for development.” Biodiversity and medicinal plants are included as one of the four thematic areas in which activities are focused.

Education and training are key areas of interest to UNU/INRA. In cooperation with other agencies of the UN, the program develops curricula and contributes to training in areas such as ecological economics, natural resource economics and environmental accounting, germplasm and biodiversity conservation, wildlife management, and taxonomy. Gender and Natural Resources is a major cross-cutting theme in the work of the institute.

Systematics Research and Training

While the demand for expertise in conservation, biodiversity, and systematics has been increasing, concern is being expressed about the human resources, especially in developing countries, available to manage and inform natural resources utilization around the globe. A 1995 workshop on Priorities in Systematics Research and Training organized by the United Kingdom Systematics Forum and held at the Linnean Society of London raised issues about the adequacy of support for systematic biology, the declining interest in systematics among students, and the decline in the teaching of systematics in many universities.

Fueled by the growing interest in biodiversity an increasing number of university departments worldwide provide training in systematics and taxonomy, often in partnership with research-oriented museums and botanical gardens. New emphases, such as work in molecular systematics, may exist in cellular, molecular, microbiology, or biochemistry programs. BIO NET-INTERNATIONAL is a global network of people and institutions that develop biosystematics capacity in developing countries. Training at all levels (in service, short courses, distance courses, and joint graduate programs) is a major focus of the network’s activities.

Conclusion

A combination of school-based learning and out of school experiences combine to provide young people with knowledge of and attitudes about biodiversity that they then take into adulthood. For those who pursue higher education, college-level courses are available in some institutions that integrate biodiversity education into larger biological, environmental, or human impacts courses. Other adults must depend on the informal education sector, with experiences provided by a variety of different institutions and media. Biodiversity education may also, in some cultures, rely on community

transmission of locally held knowledge of plants and animals of a region. Whatever the process for developing understanding, education and public awareness have been seen as crucial precursors to building support for biodiversity.

Glossary

Anthropocentrism Position that only human beings have moral worth or intrinsic value.

Ecosystem health Condition of an ecosystem, whether natural, managed, or human-dominated, that is free from influences that would damage or destroy its characteristic structures and functions.

Ecosystem integrity Condition of an ecosystem that is largely free from human interference and possesses a species composition and functional organization comparable to those of natural ecosystems in the region.

Instrumental value Value of something relative to human interests or desires.

Intrinsic value Value of something independent of its value to people.

Rights Justified claims that people respect a being's existence and important interests, and act accordingly.

Sustainability Ability of a society, institution, business, or any individual or collective human activity to continue indefinitely without depleting resources or damaging the environment.

Wilderness Large area that remains essentially unmanaged and unmodified by human beings.

Conservationists' Ethical Consensus

There is widespread disagreement in modern societies regarding the proper human relationship to the rest of the natural world. Conservationists and conservation biologists, however, mostly agree on the following ethical principles: the diversity of organisms is good; ecological complexity and natural evolution are good; the untimely extinction of populations, species, and biological communities is bad; biological diversity has great value both to people and in its own right; and human beings have both strong altruistic and strong self-interested reasons for preserving biodiversity (Primack, 2010).

Conservationists justify these principles in very different ways. One may value biodiversity because it is God's creation and testifies to God's glory; another because it is the natural culmination of evolution and global forces that have occurred over hundreds of millions of years; a third because of its value to science, perhaps humanity's noblest pursuit; a fourth because of its beauty and the enjoyment that current and future generations may take in it; a fifth because its intrinsic value grounds a strong duty to protect it, regardless of human interests; a sixth because preserving biodiversity helps preserve human life-support systems. Such justifications may be more or less anthropocentric – centered on human interests. However different their ultimate justifications, conservationists tend to accept these ethical principles and work with others to preserve biodiversity.

Difficult ethical and practical issues emerge when we ask two further kinds of questions. First, what do these general principles entail? Given a high valuation of nature and a sense of personal responsibility to help protect it, what exactly is required of us as scientists and citizens? Second, how does our concern to protect biodiversity mesh with our obligations to humans? What if they clash? Such questions come up in numerous practical contexts and must be answered, although we cannot wait for certainty or complete consensus in order to act.

Conservation Goals: Health, Integrity, Sustainability

For much of the 20th century, public and private land management goals have been primarily economic. It has become increasingly clear, however, that an exclusive focus on economic productivity leads to environmental degradation: pollution, the extinction of species, and the creation of a progressively simplified landscape (Daly, 1996). In response, laws have been passed directing government land managers to preserve the health and integrity of ecosystems. A focus on short-term economic returns also tends to undermine the long-term economic productivity of biological systems, such as forests and fisheries. Recognizing this, governments have begun to promote sustainability as an ideal in the use of natural resources. Conservationists hope that health, integrity, and sustainability specify goals concrete enough to guide us in our actions while commending themselves as basic values that a wide variety of people will share.

Health

Responding to widespread criticism of its forestry practices, Canada's Provincial Forest Ministers agreed in 1992 that "our goal is to maintain and enhance the long-term health of our forest ecosystems, for the benefit of all living things both nationally and globally" (Westra and Lemons, 1995). Government agencies around the world have similarly embraced the notion of land health. Participants in a major symposium on ecological health defined it as follows:

An ecological system is healthy and free from "distress syndrome" if it is stable and sustainable – that is, if it is active and maintains its organization and autonomy over time and is resilient to stress (Costanza *et al.*, 1992).

Just as a healthy human being is free from disease and able to perform his or her characteristic functions well, a healthy

forest or stream is free from air or water pollution, siltation, or invasions of exotic organisms. Such stresses impede or radically alter the systems' natural functions (such as photosynthesis or net primary productivity) and structure (often eliminating sensitive species and simplifying biological communities) (Table 1).

Healthy ecosystems provide both natural biodiversity and a wide array of products and services valued by humans. For this reason, economic productivity (as measured in board feet, fish caught, or crops yielded) can sometimes stand as one measure of overall ecosystem health. Rapidly declining fish catches in Lake Victoria, due to the introduction of the Nile perch, signaled a decrease in the system's health. However, economic productivity may sometimes be increased by a radical simplification of an ecosystem, as when diverse, natural forests are converted to single-species, even-aged pine plantations, or when natural prairies are converted to cattle ranches (Figure 1). Such simplified ecosystems are not necessarily economically productive in the long run, but if they are, then whether they are seen as unhealthy depends on whether preservation of native biodiversity is part of our definition of land health.

If simplified ecosystems are managed well, they may stay healthy for humans and a reduced biota, remain stable and resilient to stress, not pollute surrounding ecosystems (e.g., not dump excessive silt or fertilizer in streams), and continue to perform valuable ecosystem services. Because some relatively intensive land use is necessary for human survival and this can be done better or worse, it makes sense to apply concepts of land health to simplified ecosystems. At the same time, we must recognize that preserving as much biodiversity as possible in managed systems (croplands, lakes, forests) is desirable and that excessive simplification across a large landscape leads to extinction of species and loss of characteristic natural communities. Ecosystem health must be supplemented with the ideal of ecosystem integrity – at least in some areas (Pimentel *et al.*, 2000) (see Conservation Goals: Health, Integrity, Sustainability, below).

We should also remember an important difference between human health and ecosystem health. Individual human beings grow old, decay, and die, and while we fight this we also accept it. In contrast, we want healthy ecosystems in perpetuity, for their own good and the good of our descendants. Thus ecosystem health must also be supplemented with the ideal of ecological sustainability (see Conservation Goals: Health, Integrity, Sustainability, below).

Integrity

Amendments to the U.S. Clean Water Act of 1972 first set ecological integrity as a management goal by calling for the restoration and maintenance of “the chemical, physical, and biological integrity of the nation’s waters.” Rolston (1994) noted that “both integrity and health are combined fact-value words. Both convey the idea of wholeness and of unbroken functioning.” But ecosystem integrity implies a greater measure of freedom from past and current human manipulation and a closer approximation to natural structure and functioning than does ecosystem health. Karr and Dudley (1981) defined ecological integrity as “the capability of supporting and maintaining a balanced, integrated, adaptive community of organisms having a species composition, diversity, and functional organization comparable to that of natural habitats of the region.”

Integrity is a key environmental ideal because it encompasses the full preservation of biological diversity, including individual organisms, species, natural communities, and the ecosystem processes that have created and sustained them (Westra *et al.*, 2008). It has taken a long time for this ideal to be acknowledged, even in supposedly fully preserved areas. For example, wolves, mountain lions, and other predators were routinely shot, trapped, and poisoned in US national parks up until the 1960s. It is only in the last 10 years that wolves, once extirpated, have been reintroduced into Yellowstone National Park. For most of this century, fires were

suppressed throughout the national parks; they were perceived as dangerous to both people and forests. Over time, however, fire ecologists documented the historical role of fires in creating the natural landscape and preserving fire-dependent species of plants and animals. In response, land managers have introduced controlled burning into parks and allowed some lightning-ignited fires to burn. Improved ecological understanding and an attempt to distinguish between what is good for the ecosystem and what is comfortable or familiar for people have shown that wolves and fire belong in the parks.

The fact that ecosystems are not as strongly integrated, clearly bounded, or stable as individual organisms complicates attempts to specify ecological integrity in particular cases. It is sometimes difficult to stipulate which outside influences represent assaults on integrity rather than mere changes. Recent study suggests that many ecosystems are relatively loose assemblages of species; that these assemblages may be relatively recent and transient creations; and that even left to themselves many natural communities will not necessarily reach a

particular, invariant climax state but may instead reach any one of a number of more or less stable states, or no stable state whatsoever. If species assemblages are always changing naturally, why distinguish species that are extirpated or introduced by humans, as when conservationists reintroduce wolves in the Rockies or eradicate wild boars in the Great Smoky Mountains? If there is no one natural end point to succession, why assume that human-created early-successional stages (fields of shrubs after clear-cuts) have less integrity than naturally occurring late-successional stages (old-growth forests)?

Still, ecosystems typically go through characteristic successional stages and support characteristic (if not invariant or exact) species assemblages. Though natural species assemblages change, this usually occurs on a time-scale that allows for much stability, the development of complex interactions between organisms, and the increase of biological diversity at the landscape level. In contrast, human-induced changes typically decrease biodiversity and always lead to a landscape that is partly our creation. This loss of independence arguably marks a qualitative change in an ecosystem's natural history and a corresponding loss of ecosystem integrity (Foreman, 2004). Applying this complex concept to particular ecosystems thus involves attention to scale, knowledge of an ecosystem's particular history, and comparison with the structures and functioning of similar ecosystems. Maximizing ecological integrity involves balancing the sometimes conflicting goals of freedom from human interference and preservation of historical natural communities.

Despite these complications, the desire to restore degraded ecosystems demands robust conceptions of ecosystem integrity and health. Ecologists attempting to restore ruined pasture-lands to native prairie in Wisconsin, worked-out strip mines to forests in Appalachia, or drained lands back to wetlands in Florida, must set specific objectives (Figure 2). As with land managers seeking to limit their effects on relatively pristine areas, restorationists have taken health and integrity, defined in relation to natural baselines, as goals for restored landscapes.

Sustainability

"Live Sustainably!" has become a rallying cry in the environmental movement. Like health and integrity, sustainability is a term that blends facts and values, helping us act on our environmental convictions. At a minimum, sustainability involves preserving resources for future generations. But this minimum will not satisfy conservation biologists, who insist that part of what must be sustained is the full complement of biological diversity, for its own sake and for the benefit of humans.

Wide differences exist here. For instance, in 1987 the United Nations World Commission on Environment and Development (the Brundtland Commission) defined sustainable development as "development that meets the needs of the present without compromising the ability of future generations to meet their own needs." The focus here is wholly on human beings. On this definition the mass extinction of species is sustainable, provided future generations of people can meet their self-defined needs. Noss summarized the

shortcomings of such narrow, anthropocentric accounts of sustainability as follows:

A failure of those who promote sustainability to consider environmental and social limits to growth; an unwillingness to address the unsustainability of the current human population, much less its expected growth; a reluctance to confront the implications of the lifestyles of average citizens of the more affluent societies . . . a failure to recognize the claims of other species to their share of the planet's resources (Westra and Lemons, 1995).

Contrast the Brundtland definition with Barbier's more generous definition of sustainable development: "to maximize simultaneously the biological system goals (genetic diversity, resilience, biological productivity), economic system goals (satisfaction of basic needs, enhancement of equity, increasing useful goods and services), and social system goals (cultural diversity, institutional sustainability, social justice, participation)" (Munda, 1997). Such a definition implies a different conception of human development and a more restrained treatment of the nonhuman world than has prevailed up to this point in human history. Satisfying the basic needs of all people and creating just and flourishing societies are part of this goal; limitless wealth creation, unbounded consumerism and ever more people are not (Daly and Farley, 2011).

Conservationists are particularly concerned to keep the definition of sustainability based in ethics and biology and not solely in traditional economics (Daly, 1996). Economically based definitions often define sustainability in terms of indefinite economic growth, but in the crowded, fossil-fuel-propelled world of the 21st century, continued emphasis on economic growth will inevitably undermine ecosystem health and integrity worldwide (Speth, 2009). We cannot sustain increased consumption and increased human populations and protect biodiversity at the same time.

Management and Nonmanagement

Setting aside parks and wilderness areas where human beings are not permitted to use resources has been conservationists' most effective tool in conserving biological diversity. Here the results from conservation biology are clear. Wild areas preserve greater numbers of native species than do areas managed for agriculture or forestry. Large protected areas are more likely than smaller ones to preserve full complements of native species. Some species need large areas of habitat to preserve minimum viable populations. Some species tolerate little human disturbance. Larger areas are less likely to suffer "edge effects" that render otherwise good habitat unusable by some species (Nelson and Callicott, 2008).

A dilemma arises, however, because in order to preserve certain wild species or communities, we may have to actively manage natural areas. Rare, threatened plant populations may have to be fenced off from browsers, or new populations may need to be created from seeds or cuttings. Small, widely scattered populations of an endangered mammal may have to be gathered together to preserve genetic variety or create viable populations. Controlled burning may have to be carefully introduced into a forest or field to preserve fire-dependent species (Figure 3).

Most conservationists accept reintroductions of indigenous species into wild areas and other manipulations that have as their goal the preservation or recreation of indigenous flora and fauna. But they sharply distinguish actions that have this goal from actions that support further resource extraction or tourism development (road building, tree harvesting, construction of lodges and restaurants), which they continue to oppose in wild areas. Further, they see value in the absence of manipulation itself and tend to view the need for heroic measures in pristine areas as an indication of what has already been lost.

As a practical matter, hands-on management will often be necessary to preserve biodiversity. Even our largest natural areas are increasingly "islands" of diversity surrounded by development. These islands will likely lose species over time, as predicted by conservation biology theory and confirmed by empirical study; more native biodiversity may be preserved by augmenting populations and managing habitat. Other semi-wild areas will continue to be utilized by humans; these areas support wild species that may also need management in order to survive. Some manipulation will be needed, in perpetuity, if we are going to preserve as much biodiversity as possible.

It should be noted, however, that heroic measures and intrusive management often fail to preserve species. Skeptics

(a)

(b)

Figure 3 Conservation management: Intervention vs leave-it-alone. (a) Heathland in protected areas of Cape Cod, Massachusetts, is regularly burned to maintain open habitat and protect wildflowers and other rare species (Photograph by Dunwiddie P). (b) This old-growth stand in the Olympic National Forest in Washington is the result of many years of keeping human disturbance to an absolute minimum (Photograph by Thomas Kitchin/Tom Stack & Associates).

also warn that a casual acceptance of manipulation may lead to a loss of biodiversity, if all sorts of human purposes are allowed to vie with nature preservation on our park and forest lands. Too often, management of nature becomes a substitute for management of ourselves (Rolston, 1994). Rather than close popular trails or campgrounds in Yellowstone National Park, for example, the U.S. National Park Service exterminates “problem” grizzly bears, despite their status as an endangered species.

Arguably, too, wilderness is itself a part of biodiversity and not just a means to preserve it. Conservation biologists commonly define biodiversity to include species diversity, genetic diversity, and community diversity: the latter is defined as different biological communities and their associations with

the physical environment (the ecosystem). But if biodiversity includes biological communities and ecosystems, their disappearance or development into something essentially different constitutes a loss of biodiversity.

So, conservationists must make hard choices to protect biodiversity. For example, some models of global climate change suggest that more than 10% of the plant species in many U.S. states will not be able to survive new climatic conditions in the next few centuries – they will have to migrate northward or die out. If species are in danger of going extinct in the wild because of climate change, the last remaining individuals may have to be preserved by us; hopefully, wild populations of these species can then be reestablished in new protected areas where the climate is suitable for them. In these cases of ecological triage, we should arguably move from a wild species – not our creation, not domesticated – to a wild species, living and continuing to evolve in the wild. The goal should be a future in which species survive without having to be moved, monitored, or supported by us and in which we rein in the human overpopulation, overdevelopment, and overconsumption that make such biodiversity management necessary. By managing ourselves more wisely, we can limit the need to manage wild nature.

Biodiversity Protection and Animal Rights

Conservationists typically argue that preserving species and whole biological communities should take precedence over preserving individual animals. In practice, this means that exotic animals may be sacrificed when necessary to preserve native species and overpopulous native or exotic animals may be sacrificed to preserve land health. These positions have provoked arguments with animal rights advocates, who might seem to be conservationists’ natural allies.

For example, U.S. government agencies judged the continued existence of the endangered plant Santa Barbara live-forever (*Dudleya traskiae*) to be more valuable than the common rabbits that had been introduced on its island home. The rabbits, which fed on the plant’s fleshy leaves, were killed to stop the destruction of this fragile plant species. In another example, state officials sanctioned the culling of hundreds of deer in the Quabbin Preserve in central Massachusetts to prevent over-browsing as a way to allow tree regeneration and protect water quality. Protection of the overall health of the forest and continuation of basic ecosystem functioning (forest regeneration, water purification) outweighed the interests of individual deer.

Such practices seem mere common sense to many conservationists, but many animal rights advocates argue that they are misguided, for two reasons. First, animals (at least some higher animals) have rights or interests based on their consciousness or sentience (their ability to feel pleasure or pain). This means that we cannot sacrifice them casually for other goals, such as a healthy forest. Second, species and forests do not have rights or interests, because these complex aggregates are too loosely organized (see earlier discussion). To sacrifice the real interests of a higher animal to the bogus interests of a species or biological community is thus ethically mistaken (Schmidtz and Willott, 2011).

Conservationists' answer that as we learn more about biodiversity, we realize that its greatest value lies not in individuals but in the wholes that those individuals help constitute. It is the species that persists and evolves rather than the individuals, which come and go. It is the natural community that sustains and generates new forms of life. While an ethics based on individual rights best specifies appropriate human interactions, a less individualistic ethics is needed to properly value the natural world (Westra *et al.*, 2008).

This ethical shift seems to be necessary for effective conservation. However, animal rights advocates have given strong arguments for respecting individual higher animals such as cats, rabbits, and wild horses. Conservationists, who usually value species over individuals, may concede that individual animals should not be sacrificed casually, but only if it truly is necessary to preserve species or the health of biological communities. They might add that individual animals should always be culled humanely, that is, with a minimum of suffering. This would rule out most trapping and much sport hunting, although these activities are routinely defended on conservation grounds.

For example, Quabbin Preserve managers might carefully monitor deer populations and tree regeneration and authorize hunting where appropriate. All deer kills would have to be performed humanely, and in some years no hunts might be authorized. Whereas a traditional wildlife management position would authorize hunting game birds and trapping beavers, mink, and muskrats as long as this was done sustainably, a position responsive to animal welfare might not allow any of these activities, unless they could be justified with reference to the good of the forests or particular species.

Conservation and animal rights ethics both typically lead beyond anthropocentrism – the belief that only human interests matter – and they are usually complementary. For example, a concern for individual animals leads logically to vegetarianism, which prevents much animal suffering and bloodshed. But since “eating lower on the food chain” is less energy, water, and land-use intensive, it also helps conserve resources and preserve biodiversity. Limiting consumption and distinguishing between needs, comforts, and luxuries are precisely what are needed to carry out both ethics. Nothing prevents individuals from living highly consistent lives that incorporate both ideals. We may act to limit animal suffering and preserve wild nature so that the entire realm of biodiversity can flourish.

Biodiversity Protection and Human Rights

Conservationists often argue that individual organisms, species, and biological communities have intrinsic value – that is, value in addition to their usefulness to human beings – that obliges us to preserve them. This means human interests should sometimes be sacrificed to preserve biodiversity. For example, a developer should not build a housing project that destroys critical habitat for an endangered songbird species – whether or not it is legal to do so. The continued existence of this species is more important than the developer's profits. His less-than-vital interests should be foregone or pursued in ways that do not sacrifice something infinitely more valuable: a

natural species. In many cases, however, preserving biodiversity and furthering human interests are complementary goals, especially if we take a broad view of human interests. Present and future generations have strong material, esthetic, scientific, recreational, and spiritual interests in preserving biodiversity.

Owls and People

The coniferous forests of the US Pacific Northwest are some of the most majestic on earth, with thousand-year-old trees towering over crystal clear streams filled with salmon. As commercial timber harvesting escalated after World War II, the big trees fell and species dependent on old-growth forests such as the northern spotted owl (*Strix occidentalis caurina*) (Figure 4), the marbled murrelet (*Brachyramphus marmoratus*), and various salmon species (*Oncorhynchus* spp.) declined dramatically. In response, environmentalists staged logging blockades and tree sittings during the 1980s and successfully sued the U.S. Forest Service under the Endangered Species Act, resulting in drastic limitations on tree harvests in the 1990s.

This contentious political battle was often billed as “owls versus people,” but such a simplistic formulation was misleading. Reduced harvests resulted in the loss of thousands of logging jobs, but some reduction was inevitable, given unsustainably high harvest levels based on the one-time cutting of thousand-year-old trees. Logging reductions helped preserve and create jobs in fishing and tourism and enhanced watershed maintenance, flood control and other objectives. A calculation based on the full spectrum of long-term human interests would likely have resulted in substantially decreased timber harvesting. Still, old-growth forests do have great economic value as timber, and preserving more in reserves rather than cutting the big trees and moving to high-yield forest plantations may indeed lead to lower profits for industry and fewer overall jobs.

Are such trade-offs ever justifiable to prevent the extinction of species or important biological communities? Forestry industry executives and loggers' unions said no. The interests of a logger in supporting his family should supersede the interests of animals or trees. Logging restrictions to protect other species are wrong because they lead to real human hardship for loggers and their communities. Environmentalists insisted that more logging jobs and higher corporate profits did not outweigh the permanent loss of species and the old-growth temperate rain forest itself. They also noted that industry and government had made no efforts to preserve logging and mill jobs when technological changes, log exports, or over-harvesting had led to job losses in the past (see Figure 4).

These considerations suggest a solution to the dilemma: harness the economic system to maximize both human interests and biodiversity protection. Whether we focus on intrinsic or instrumental value, the human communities of the Pacific Northwest have an interest in preserving their remaining old-growth forests. Fortunately, the regional economy generates enough wealth to provide laid-off workers with guaranteed health care, generous severance pay and job retraining for those who want it. The big trees could be preserved and displaced workers supported by their fellow citizens. Such a course would not reconcile all conflicting interests or solve all problems:

(a)

(b)

Figure 4 Natives. (a) The northern spotted owl is an indicator species for old-growth forests of the Pacific Northwest, a habitat coveted for its rich timber stands. (b) Demonstrators protest government and corporate policies that destroy forests and threaten species extinctions.

economic winners would have to be taxed to support economic losers, some loggers would have to give up a valued livelihood, and some businesses would have to forego profits or even fold. But many of the costs of environmental protection would be borne by society as a whole, which benefits from the preservation of biodiversity.

Property Rights

When environmentalists won suits to limit logging in the Pacific Northwest, the resulting bans affected both private and public lands. To some observers, the restrictions on private lands were unjustified. In their view, the right to own and control property is essential. Dictating to individuals or corporations what they can or cannot do on their own land is seen as intolerable, abridging their freedom. In devising a plan

to continue tree harvesting in the region, the US government focused preservation efforts on public lands, allowing private landowners greater freedom.

Does private property ownership give owners unlimited control over their land, even if their actions contribute to the extinction of a rare or endangered species? Historically it often has, but morally it does not. Both the intrinsic value of species and duties to our fellow citizens to preserve a common biological heritage argue against such actions, regardless of how much profit must be foregone. Land ownership confers both rights and responsibilities.

What then of a small landowner who needs to cut an old-growth stand in order to send a child to college or keep the land in the family? Clearly as the need becomes greater, the ethical justification increases, even if some loss of biodiversity occurs. Hopefully, though, this small owner is not so poor that he must view his land solely as a money-generator. The ideal is some compromise in which the land is used in responsible ways that also preserve biological diversity.

Finally, it is important to distinguish between individual small owners and the large timber corporations that rival some national governments in the size of their landholdings. Arguments for preserving the freedom of small forest owners do not justify laissez-faire policies for large corporate landowners. Corporate managers' personal freedoms are not at stake in the same way and their management decisions have vastly greater effects on natural and human communities. No government that cares about preserving its citizens' biological heritage will fail to regulate the environmental impacts of large corporate landowners.

Wilderness in Less-developed Countries

Recently, some writers have argued that biodiversity preservation is a specifically North American or Western preoccupation, whose promotion in less-developed nations amounts to cultural imperialism. According to Ramachandra Guha, for example, wilderness preservation is inappropriate and unnecessary in these countries, whose peoples face more pressing environmental issues centered on meeting basic human needs. He argues that:

the setting aside of wilderness areas has resulted in a direct transfer of resources from the poor to the rich [in the less-developed nations]. Thus, Project Tiger, a network of parks hailed by the international conservation community as an outstanding success, sharply posits the interests of the tiger against those of poor peasants living in and around the reserve. The designation of tiger reserves was made possible only by the physical displacement of existing villages and their inhabitants; their management requires the continuing exclusion of peasants and livestock ... transplanting the American system of national parks onto Indian soil. In no case have the needs of the local population been taken into account, and as in many parts of Africa, the designated wildlands are managed primarily for the benefit of rich tourists (Schmidt and Willott, 2011).

There is some truth in Guha's claims. Several of Project Tiger's reserves were built around old hunting preserves from which the poor had long been excluded, while others were set up on former state or communally owned lands and displaced numerous villages, causing real hardship to thousands.

Grazing and tree cutting in the core areas of the reserves were prohibited, both to limit human–tiger conflicts and to preserve a more complete flora and fauna.

On the other hand, India's wild tigers were clearly headed for extinction when Project Tiger was undertaken: between 1900 and 1972, the year it was initiated, the tiger population fell from tens of thousands to just 1800 individuals. Strictly limiting tiger hunting had not halted this decline. Habitat conservation was obviously necessary to protect the tigers over the long term and, given the requirements of tigers and their inevitable conflicts with humans, this had to involve some displacement and restrictions on local inhabitants.

Should Project Tiger have been attempted? Guha suggests not: he believes it represented an unjust appropriation of the resources of poor people. At the same time, a focus on tigers went hand in hand with ignoring "environmental problems that impinge far more directly on the lives of the poor – for example, fuel, fodder, water shortages, soil erosion, and air and water pollution . . . [which are] far more pressing environmental problems within the Third World" (ibid.). Others disagree, arguing that habitat preservation and restrictions on human economic use of this habitat were necessary and appropriate responses to the imminent extinction of the Bengal tiger. This would have been a great cultural loss to the Indian people and an unjust destruction of an intrinsically valuable species. Many conservationists do not accept the extinction of species as a less pressing problem than those mentioned by Guha, because they do not accept his exclusive focus on human interests, nor his narrow definition of those interests (Figure 5).

In recent decades, wildlife managers around the world have been experimenting with ways to give local people a stake in the success of wildlife and park conservation, with encouraging results. In Africa, these efforts have included disbursing a percentage of park revenues directly to local villages, increasing efforts to hire local inhabitants as guides and forest wardens, compensating for crop damage done by wildlife straying outside of parks, and giving local people input into protected areas management. In India, beginning in the late 1980s, the Ranthambhore Foundation and other groups began promoting sustainable development in the villages on the periphery of the Project Tiger reserves. This has included replanting denuded forests and improving fodder – to decrease pressure to graze and cut firewood within the reserves – as well as efforts to educate local children in natural history and conservation principles.

Justice demands that local people be treated with respect and their interests considered in all programs to protect wildlife and wildlands. Such respect and consideration will not solve all problems, however, particularly in a country as overpopulated as India, whose human population has increased from 350 million people at independence in 1947 to 1.15 billion people in 2010. In some instances, if we want to preserve wildlife, we will have to sacrifice human interests.

Overall, securing human rights and furthering essential human interests should strengthen efforts to preserve biodiversity. The 1972 United Nations Conference on the Human Environment affirmed that all human beings have fundamental rights to clean air, clean water, pure food, and a healthy environment generally. Preserving these environmental goods

Figure 5 Valuing biodiversity in less-developed countries. Buddhist priests in Thailand offer prayers and blessings to protect communal forests and sacred groves from commercial logging operations.

tends to benefit wildlife and natural systems as well. Environmentalists have also argued that future generations have a right to know, explore, and celebrate an undiminished natural heritage (Carson, 1962). Respect for this right would halt many environmentally destructive development projects. Natural areas are often threatened by remote governments and corporate managers, while their strongest defenders tend to be local inhabitants who know and love them. Securing rights and political power for local inhabitants should help preserve these areas. Safeguarding human rights and preserving biodiversity are only compatible, however, if people are willing to limit their numbers and their demands on nature. Empowering ever more people with a belief in their right to ever higher consumption is a recipe for ecological disaster.

The Ideal of the Conservation Biologist

Four hundred years ago, modern science's great pioneer and prophet Francis Bacon located the primary value of science in its creation of a powerful technology for controlling nature. "The End of our Foundation is the knowledge of Causes, and secret motions of things," Bacon wrote in *The New Atlantis*, "and the enlarging of the bounds of Human Empire, to the effecting of all things possible." Without denying science's utilitarian benefits, conservation biologists attempt to move in a different direction, developing the knowledge needed to preserve nature rather than to change, control, or exploit it.

Figure 6 Role models. Primatologists Dian Fossey (left), Jane Goodall (center), and Birute Galdikas began by studying animal behavior, but eventually devoted themselves to conservation activism.

Both historical and contemporary examples attest that science can be carried out in this spirit. Aldo Leopold and Rachel Carson, Paul Ehrlich and E. O. Wilson, and many others from a wide variety of disciplines and backgrounds have combined contributions to science, literature, education, public policy, and conservation. The challenge for the scientist is to personally cultivate a loving knowledge of nature and to speak about nature in a way that promotes its celebration and protection (Figure 6).

Professional Decisions

If conservation biologists are to help successfully preserve biodiversity, they must take on a variety of active roles in addition to their scientific pursuits. For a start, they must become more effective educators in public forums. Conservation biologists often teach college students and write technical papers addressing environmental issues, but they need to reach a wider range of people by also speaking in villages, parks, elementary and secondary schools, and neighborhood gatherings. They must spend more time engaging all forms of mass media: writing articles and editorials for newspapers and magazines, blogging on popular websites, and speaking on radio and television. Because tenure, promotion, and professional prestige often accrue for technical work and peer-reviewed science but not for more practical or popularizing efforts, conservation biologists may face difficult choices when deciding whether to devote time to the latter.

Similarly, research projects describing habitat requirements or methods of transplanting an endangered species may have important conservation implications, but little potential to make basic advances in ecological or biological theory. Again, hard choices between professional glory and conservation

usefulness may be necessary. As conservation biology becomes more established as a discipline, the system of rewards in place for practical conservation work will hopefully improve. Tenure and promotion committees at universities should acknowledge the value of community outreach and research that addresses local conservation issues.

Conservation biologists must also become politically active. Involvement in the political process allows conservation biologists to help pass new laws to preserve biological diversity, or argue against harmful legislation. Though politics may be time-consuming and tedious, it is the only way to accomplish major conservation goals, such as creating new parks and reserves (Lear, 1997). Conservation biologists also need to master the language and methods of the legal process and form effective alliances with environmental lawyers, citizen groups, and politicians. With their detailed knowledge of specific organisms and ecosystems, biologists are well placed to alert the general public to threats to biodiversity. They may also present this natural heritage in an appealing and inspiring way that leads to its preservation.

Such outreach and activism take time away from the pursuit of pure science. But many believe that at this point in human history, we no longer have the luxury to pursue knowledge for its own sake. To learn about biological diversity today is to learn about the threats facing it (Wilson, 2003). These threats demand an active response.

Fortunately, there is room for many types of work within conservation biology. Field and laboratory biologists who perform detailed natural history studies and genetic analyses of endangered species are necessary; so are hands-on managers who put together species recovery programs and coordinate interagency partnerships to facilitate them; so are teachers and writers who popularize wild nature; and so are political firebrands who alert the public to biodiversity losses and corporate environmental crimes.

Personal Choices

What about conservation biologists' private lives? Should a conservation biologist own a sports utility vehicle, for example? It gets terrible gas mileage, yet it might greatly facilitate her field work. Should a conservation biologist take a spectacular eco-tourist vacation to Amazonia? The trip uses prodigious resources, yet he might gather information and take pictures to educate audiences back home about important environmental issues. Then again, such reasoning may hide our real motivations: to drive in maximum comfort, to travel and enjoy ourselves. There is nothing wrong with comfort and enjoyment per se, but such high-consumption activities take a great toll on world biodiversity. Perhaps a conservation biologist should set a more restrained example.

Integrity is a key human virtue. It means living in conformity with our values and resolutely striving toward worthwhile goals. As spokespeople for biodiversity protection, conservation biologists will make more converts if they practice conservation in their own lives. Above all, this means limiting their personal consumption of resources through owning fewer things, recycling, avoiding unnecessary air travel, and taking other appropriate actions (Alexander, 2009). However, it is not necessary to put on a hair shirt or engage in

a quest for absolute purity. Showing that a life devoted to conservation can be stimulating and enjoyable is itself an important conservation message.

Should a conservation biologist dive into political debates? Give up time in the lab to meet with a group of concerned citizens? Drive a car to work? Eat meat? Have more than one child? These difficult professional and personal questions must be faced by conservation biologists and other committed conservationists. Responses may legitimately differ, but some are much better than others; indeed, some are inspiring (Wilson, 1994).

Ultimately, the fate of world biodiversity depends on two kinds of efforts. First, direct work such as habitat preservation, species reintroductions, ecosystem restoration, environmental litigation on behalf of other species, and the like. Second, preserving wild nature depends on creating societies that limit human numbers, consumption and economic growth, in order to enable us to set aside room and resources for other species. The creation of such societies is the greatest challenge facing biodiversity proponents today.

Government Legislation and Regulations in the United States

Kathryn A Saterson, U.S. Environmental Protection Agency, NC, USA

Published by Elsevier Inc.

Glossary

Case law Interpretations of the US Constitution, statutes, and regulations provided by the judicial branches of US federal or state government. Such interpretations are provided when two or more parties disagree as to the meaning of a law in a specific context and bring it to the courts to decide.

Constitution A statement of the principles governing a nation or state.

Critical Habitat Habitat required to maintain a threatened or endangered species.

Executive order A directive from the US president, or a state governor, specifying actions by government officials and agencies. State and federal executive orders often describe how to administer a provision of a statute, treaty, or the constitution and usually have the force of law.

Precautionary principle An approach to regulations and treaties based on consideration of the fact that when there is a threat of serious or irreversible damage, lack of full

scientific certainty about outcomes should not be used as a reason to postpone measures to avoid that environmental damage.

Regulations Rules and administrative codes required by statutes and issued by local, state, and federal government agencies. Regulations have the force of law since they are adopted under the authority granted by statutes.

Statutes or legislation Laws passed by the legislative branch of US federal or state governments. The US Congress passes federal laws and state legislatures pass state laws. Local laws are usually called municipal ordinances.

Treaties Multilateral agreements between or among nations regarding the actions of each national government. Only rarely do treaties address the actions of private institutions. International treaties, often called "conventions," are signed (entered into) in the US by the President but must be ratified by the Senate for the US to be an official party to a treaty. Treaties supersede federal, state, and local laws that might have contradictory goals.

Introduction

For centuries, customary or traditional laws have governed the use of biological resources throughout the world. The systems of customary law in traditional cultures often dictate limits on how much of a specific biological resource can be used and in what seasons. In many societies, an individual's rights to biodiversity are not always linked to land tenure. As traditional societies are becoming more integrated into national and global markets and political systems, traditional knowledge and laws are being lost. As human population levels increase in all societies, voluntary actions governed by cultural practices are frequently insufficient to protect biodiversity, leading to an increasing reliance on the creation and enforcement of government legislation and regulation to protect biodiversity.

A variety of motivations have led to creation of legislation intended to help conserve biodiversity. Early legislation was primarily aimed at protecting biodiversity as an economic resource for humans (e.g., for hunting or agriculture). Recent laws, and amendments to earlier laws, have included other reasons, such as the value of biological diversity to overall ecosystem health and the intrinsic value of species. Although US national parks were originally created primarily for scenic and recreational values, the 1916 National Park Act identified conservation of wildlife as an important goal of parks.

Laws and regulations to protect biological diversity can aim to influence actions undertaken by a range of actors (government agencies, private corporations, and individual citizens) and to affect a range of resource types (animals, plants, water, land, and specific habitats and ecosystems) with differing

ownership and resource control (public and private). The success and evolution of legislation and regulation in the US are in part a reflection of the actions of nongovernmental organizations, corporations, and others who lobby for (and against) new or amended legislation, oversee how agencies implement legislation, and use the judicial system to help ensure that laws are enforced and interpreted appropriately.

All laws and regulations in the US are based on rights found in the US Constitution. The federal government derives its authority to regulate wildlife from its constitutional authority to regulate commerce, to protect its own property (federal lands) and to make treaties. When federal laws conflict with state laws, the federal laws generally take precedence.

Many advocates of the right to private property, also supported by the US Constitution, view legislation to protect biodiversity as sometimes conflicting with their right to private property. The Fifth Amendment to the Constitution requires that when private property is taken for public use (whether to benefit public safety, create roads, protect wildlife, or for any other purpose) there must be "just compensation." Most state and federal case laws indicate that restrictions on killing wildlife are not a sufficient taking of private property to require compensation by the government (Bean and Rowland, 1997).

Despite the large number of environmental laws and regulations that now exist, and the many positive impacts that they have had, these positive steps have been insufficient to prevent the loss of biodiversity. Some argue that federal and state governments give greater weight to protecting current economic growth and private property rights than to protecting biodiversity because of a lack of constitutional authority to protect future generations. Some conservationists

advocate an amendment to the US Constitution that obligates the government to protect biodiversity for future generations. Many other nations, and a number of states in the US require conservation of nature in their constitutions.

One of the controversial issues confronting the agencies and courts in implementing all the legislation described in this article is determining how the laws apply to American Indian reservations, which are covered under separate treaties, and to traditional subsistence use of biodiversity by Alaskan natives. Balancing the needs of individuals who depend on biological resources for food, shelter, and other benefits with the need to protect biodiversity for current and future societies is an issue with both legal and ethical challenges.

This article will summarize only legislation and regulations that aim directly to conserve biodiversity. **Table 1** presents a summary of selected laws with provisions that are intended to help conserve biodiversity. There are many additional

environmental and other laws that can have more indirect positive impacts on biodiversity, for example, controlling air pollution (Clean Air Act), water pollution (Clean Water Act), hazardous waste (Resource Conservation and Recovery Act), global climate (Global Climate Change Convention), trade (General Agreement on Tariffs and Trade) or creating conservation incentives through tax policies (Internal Revenue Code). This article will also not address the specific federal, state, and local programs (often resulting from legislation) that can help to conserve biodiversity.

International Treaties

International agreements are important for conserving biodiversity because many species have very large natural ranges or migrate between countries, most habitats and ecosystems

Table 1 Selected legislation intended to help protect biological diversity

Law (year) ^a	Purpose
<i>Multilateral International Agreements</i>	
International Convention for the Regulation of Whaling (1946)	To conserve whales for the whaling industry. Created the International Whaling Commission which designates protected whale species and hunting limits
Convention on International Trade in Endangered Species of Wild Fauna and Flora (CITES, 1973)	Prohibits and regulates international trade of specified plants and animals
Convention on Biological Diversity (CBD, 1993)	Encourages nations to conserve, use, and share the benefits from conservation of genetic, species, and ecosystem levels of biodiversity. As of 2011, the US had signed but not ratified the CBD
Convention on wetlands of international importance (Ramsar Convention 1971)	Encourages nations to designate wetlands of international importance and to conserve and wisely use wetlands
International Undertaking on Plant genetic Resources (2000)	To ensure the conservation of plant genetic resources used for food and agriculture and the equitable sharing of benefits
<i>U.S. Federal Laws</i>	
Lacey Act (1900)	Prohibits commerce in wildlife injurious to agriculture and in wild animals and some plants taken in violation of US and foreign laws
National Park Service Act (1916)	Requires conservation of scenery, natural and historic objects, and wildlife in national parks and other protected areas for public benefit
Migratory Bird Treaty Act (1918)	Implements treaties with Canada, Mexico, Japan, and the Soviet Union to establish hunting seasons and protect habitat for migratory birds
Bald Eagle Protection Act (1940)	Prohibits killing or possessing bald and golden eagles, their nests, or parts
US Agricultural Research and Marketing Act (1946)	Requires collecting, preserving, and disseminating genetic material important to US agriculture
Foreign Assistance Act (1962)	Requires that US foreign aid to developing nations helps to protect biodiversity and tropical forests, and that development projects generally avoid adverse impacts on biodiversity
National Environmental Policy Act (1969) (signed by the president in January 1970)	Requires Environmental Impact Statements for federal programmatic and site-specific actions
Marine Mammal Protection Act (1972)	Creates a moratorium on importing marine mammals and limits taking of US marine mammals
Endangered Species Act (1973)	Prohibits or restricts taking of endangered or threatened species, requires federal agencies to protect their critical habitat, and regulates their trade; requires evaluation of the impact of federal projects on endangered and threatened species
Fishery Conservation and Management Act (1976)	Requires plans from state/federal councils to manage fisheries in a 200 mile offshore exclusive economic zone to ensure a maximum sustainable yield
National Forest Management Act (1976)	Requires management plans for all national forests, including conservation of a diversity of plant and animal communities
Wild Bird Conservation Act (1992)	Limits imports of exotic birds to protect wild populations in country of origin and reduce inhumane treatment of birds
National Wildlife Refuge System Improvement Act (1997)	Requires that National Wildlife Refuge System conserve fish, wildlife, plants, and their habitat while maintaining the biological integrity, diversity, and environmental health of the system

^aThis is the year legislation was first passed. All laws shown have been amended subsequent to passage. The stated purpose may include objectives added in the subsequent amendments or may not include all the purposes of the law.

do not follow national boundaries, and the earth is increasingly globalized in trade and movements of people. Under international treaties, the ratifying countries agree to take specific actions at the national level. Although the earliest international treaties reflected concerns that one nation might overexploit a species that many nations found economically important, recent treaties have acknowledged the importance of conserving all levels of biodiversity, whether or not there is an immediate economic value. Ratification of a treaty by each country is voluntary, and enforcement is often difficult. The US is signatory to many international treaties relating to biodiversity, some dating back to the early 1900s.

International Convention for the Regulation of Whaling (1946)

The major nations then involved in whaling (including the US, Japan, and the Soviet Union) were party to the 1946 Convention to Regulate Whaling, which prohibits killing calves, immature whales, or females accompanied by calves and encourages using as much of the killed whales as possible. The convention created the International Whaling Commission and gave it the authority to designate protected species and to establish hunting methods and seasons, size limits, and take limits. The convention had the conflicting goals of both conserving whale stocks and further developing the whaling industry. Most species of whales continued to decline dramatically until a 10-year moratorium on commercial whaling was agreed to by signatory countries in 1982 and went into effect in 1986. By that time, only Japan, the Soviet Union, and Norway were still whaling. The moratorium is still in effect, although it is not adhered to by Norway, and many countries continue to take whales for the “research purposes” allowed for under the convention. Iceland withdrew from the convention in 1992 (Nagle and Ruhl, 2006). The International Whaling Commission, established by the Convention, sets the aboriginal subsistence catch limits for aboriginal communities in the US, Canada, Greenland, and St. Vincent and the Grenadines.

The Convention on International Trade in Endangered Species of Wild Fauna and Flora (CITES) (1973)

The Convention on International Trade in Endangered Species (CITES), which was introduced in 1973 and entered into force in 1975, prohibits international trade in endangered species by assigning each protected species to one of three lists. Appendix I lists “all species threatened with extinction which are or may be affected by trade.” They cannot be traded primarily for commercial purposes, and trade in the species cannot be detrimental to the species survival. Trade in Appendix I species requires both import and export permits approved by the “management authority and scientific authority” of the nations involved (the secretary of interior in the case of the US). The permit has to certify that the specimen was obtained legally, it can be shipped without risk of cruel treatment or harming the health of the specimen, and the trade is not detrimental to survival of the species.

Species listed in Appendix II are not necessarily currently threatened, but unregulated trade could jeopardize their survival. Two-thirds of the parties to CITES must agree in order to add or remove a species from Appendix I and II lists. Any nation can unilaterally add or remove a species from Appendix III if it believes that cooperation from other nations is needed to control trade in a vulnerable species under their jurisdiction. Only export permits are required for Appendix II and III species. The precautionary principle was explicitly endorsed at the Ninth Conference of the parties to CITES in 1994 (Dickson, 1999). By 2011, more than 175 countries had ratified the CITES treaty.

Convention on Biological Diversity (1993)

The International Union for the Conservation of Nature began encouraging the creation of a global biodiversity treaty in the early 1980s. The United Nations Environment Program led the process of creating the convention, which was agreed to in 1992 and entered into force in 1993. By 2011, 193 countries had ratified the treaty. The US signed the Convention on Biological Diversity (CBD) in 1993, but it has not yet been ratified by two-thirds of the Senate. Until ratification, federal executive agencies are expected to conform with the treaty to the extent possible, but it is not recognized as law in federal and state courts.

The CBD outlines objectives for the conservation, sustainable use, and equitable sharing of the benefits from biodiversity. Signatory countries are called on to develop national strategies for protection of biodiversity, establish a system of protected areas, conduct environmental assessments of projects in order to prevent adverse impacts on biodiversity, enact laws regulating conditions of access to genetic resources, and support a financial mechanism for developing countries to obtain grants to assist in meeting the terms of the treaty. The convention supports conservation of agrobiodiversity (the plants and animals that contribute to food security for humans) as well as wild biodiversity. The importance of habitat conservation and of controlling alien species is acknowledged in the treaty.

Some of the most discussed provisions of the treaty (and the basis for the US reluctance to ratify it as of 1999) are those concerning access to genetic resources and the “intellectual property rights” resulting from commercial use of genetic resources (Bass, 1999). Countries with large biotechnology industries (e.g., pharmaceutical and agribusiness) supported continued open access to genetic resources (often obtained from flora in other nations), whereas countries supplying biodiversity to the industry wanted to share the profits to help ensure continued protection of biodiversity. The treaty both acknowledges each nation’s sovereign control of its biodiversity and encourages access to genetic resources by other contracting parties.

The 2010 meeting of the 10th Conference of the Parties (COP) for the CBD supported the establishment of the Intergovernmental Platform on Biodiversity and Ecosystem Services (IPBES), which will be coordinated by the United Nations Environment Program. The IPBES is a mechanism proposed to further strengthen the science-policy interface on

biodiversity and ecosystem services. By evaluating the scientific consequences of real policy options for biodiversity, the IPBES will contribute to improved legislation and regulation to protect biodiversity (Perrings *et al.*, 2011).

National Legislation

Most national laws discussed here are primarily concerned with actions influencing biodiversity in the US. A few, including the Foreign Assistance Act, legislate how actions of the US government relate to conservation in other countries. The US states were solely responsible for conserving wildlife until states urged the federal government to pass the Lacey Act in 1900. States still retain primary responsibility for biodiversity. The role of the federal government is limited to managing federal lands; conserving economically important genetic resources; protecting migratory waterfowl, marine species, birds of prey, and endangered and threatened species; and enforcing international treaties. The following discussion describes US laws that support conservation at the genetic, species, and ecosystem levels according to their primary purpose. Such divisions are arbitrary to a degree since genes are best conserved in the organisms in which they exist, and species depend on their habitats for survival.

Conservation of Genetic Resources

Federal laws regarding genetic resources are primarily concerned with conservation of varieties of economically important domesticated plants and animals, with some attention to “wild genetic resources,” for example, wild relatives of plants or animals known to be economically important. For wild species, legislation is more concerned with access to genetic resources and sharing of benefits if those resources end up being economically valuable. In 1990, an amendment to the 1946 US Agricultural Research and Marketing Act modified the National Genetic Resources Program in the Agricultural Research Service in the Department of Agriculture. The purpose of this program is to collect, preserve, and disseminate genetic material that is important to American agricultural production. This amendment expanded the types of genetic resources in the program to include silvicultural species, animals, and aquatic and microbiological organisms. Congress authorized creation of the National Seed Storage Laboratory in Colorado by the US Department of Agriculture. Although this gene bank is world renowned for the variety of agricultural species it contains, it has been criticized for inadequately maintaining seed from wild relatives of important crops.

Conservation of Species

The earliest federal wildlife legislation in the US was concerned with species, both migratory and nonmigratory, with ranges that went beyond state boundaries. Most early conservation legislation emphasized regulation of consumptive uses of species, such as hunting and fishing, to protect charismatic species such as eagles or bison. By the 1970s, Congress was aware that habitat degradation is a significant threat to biodiversity; this is

reflected in the habitat conservation provisions of the Endangered Species Act and in the increase in laws concerning habitats described in the Section Conservation of Habitats and Ecosystems.

Lacey Act of 1900

The Lacey Act was created to strengthen the ability of states to protect wildlife by regulating interstate commerce in game birds and wild birds. The Lacey Act now also prohibits importing all wildlife and some plants that were taken contrary to the laws of another country. The original act also aimed to protect US agricultural and horticultural interests by prohibiting the import of injurious foreign wildlife, including mongooses, English sparrows, and other birds and animals. Later amendments broadened the definition of injurious wildlife to include wild birds, wild mammals, fish, amphibians, and reptiles and their eggs, and the protected interests were also expanded to include humans, forestry, and US wildlife resources. The 1981 amendments also increased the maximum penalties and lowered the standard of proof for a violation, making the Lacey Act one of the laws most frequently used by federal law enforcement officials to protect wildlife (Bean and Rowland, 1997).

Laws Controlling the Introduction of Nonnative Species

One of the major threats to biodiversity is the introduction of nonnative species to new habitats, intentionally or by accident. The federal authority to regulate interstate commerce led to creation of the Federal Noxious Weed Act of 1974 and the Nonindigenous Aquatic Nuisance Prevention and Control Act of 1990. The Noxious Weed Act gives the secretary of agriculture authority to regulate both foreign imports and interstate commerce in potentially harmful plants, defined as plants of foreign origin that can directly or indirectly injure agriculture, natural fish, and wildlife resources, or public health. Amendments in 1990 gave authority to the Fish and Wildlife Service, the National Park Service, and the Bureau of Land Management to control undesirable plants on their lands.

The accidental introduction of the economically destructive zebra mussel into US waters when a ship's ballast water was released led Congress to create the Nonindigenous Aquatic Nuisance Prevention and Control Act in 1990. This act covers any plant, animal, or other “viable biological material,” such as a virus, that disperses to an aquatic ecosystem in which it is not historically found. In contrast to the Lacey Act provisions, a nonindigenous species does not have to be from a foreign country. To be termed a nuisance, a nonindigenous species must threaten the abundance or diversity of native species or the ecological stability or commercial productivity of the infested waters. The act mandates creation of a task force to implement a program to prevent the introduction and dispersal of aquatic nuisance species, but it does not specify who determines which species are a nuisance (Bean and Rowland, 1997).

Birds

Migratory Bird Treaty Act of 1918

This act was passed to implement a treaty signed in 1916 between the US and Great Britain with the aim of conserving

birds that migrate between the US and Canada. The treaty establishes closed seasons for hunting and prohibits taking of nests or eggs (except for scientific purposes) for three groups of migratory birds (game, insectivorous, and nongame – a classification that includes almost all birds). The act also implements treaties signed with Mexico in 1936, Japan in 1972, and the Soviet Union in 1976. The latter two treaties include provisions for protecting bird habitat, for example, from pollution. Numerous cases have resulted in judicial interpretations that “taking” under the treaty act does not include habitat destruction. The act was successful in supporting the 1991 requirement that migratory waterfowl not be hunted with lead shot. The courts have rejected landowner claims that the hunting prohibitions under this act are unlawful “takings” of their private property (Bean and Rowland, 1997).

Bald Eagle Protection Act of 1940

The Bald Eagle Protection Act prohibits killing or possessing bald eagles, their nests, or any part of the eagle. The secretary of interior could approve exceptions for scientific and educational purposes. A 1962 amendment added the same protections for golden eagles and authorized the secretary to permit taking of bald and golden eagles by Indian tribes only for religious purposes. A 1972 amendment of the act expanded the definition of prohibited taking to include poisoning.

Wild Bird Conservation Act of 1992

The US is the largest importer of wild birds in the world. It is estimated that as many as 50% of captured exotic wild birds die even before they leave the country of origin, and another 15% die in transit to the US (Bean and Rowland, 1997). The goal of the Wild Bird Conservation Act is to promote conservation of birds not indigenous to the US by (1) limiting or prohibiting imports of nonindigenous birds in order to reduce depletion of wild populations and reduce inhumane treatment of birds in transit, (2) ensuring that trade is biologically sustainable, and (3) assisting in wild bird conservation programs in the country of origin. Congress found that CITES was not effective in decreasing the rate of loss of wild bird populations because many signatory exporting countries were unable to implement it adequately. The act allows the secretary of interior to declare a moratorium on importing any exotic bird listed on any CITES appendix and to permit exceptions for scientific purposes.

Marine Mammal Protection Act of 1972

The Marine Mammal Protection Act (MMPA) replaced individual state authorities and programs concerning marine mammals and created a moratorium on importing marine mammals to the US and on taking of US marine mammals. Taking was defined to include attempts to harass, hunt, capture, kill, and (after later amendments) feed marine mammals in the wild. Responsibility for implementing the act rests with the secretary of commerce for (1) incidental take of mammals during commercial fishing, (2) all Cetacea (whales and porpoises), and (3) all Pinnipedia (seals) except for walrus. The secretary of interior implements the MMPA for all other marine mammals, including manatees, polar bears, sea otters, and walrus. Like most environmental legislation, the MMPA

reflects a compromise between many interest groups: Commercial interests wanting to protect an economic product, scientists who valued marine species and their role in marine ecosystems, and animal welfare groups wanting to protect marine mammals for their individual and intrinsic value.

The MMPA outlines management principles that include maintaining the health and stability of marine ecosystems and the “optimum sustainable population” for all marine mammals as well as the “maximum sustainable yield” for commercially exploited species. The taking prohibitions allow many exceptions; one that received the most attention was the controversial allowance for “incidental taking” during commercial fishing operations. At the time the act was passed, more than 5 million dolphins had died accidentally by drowning in purse-seining nets used to catch tuna (Bean and Rowland, 1997). Beginning in 1976, a series of regulations set quotas on how many dolphins could be killed incidentally by US tuna fishing boats. In 1984, amendments sought to ensure that countries exporting tuna to the US had kept incidental dolphin kills as low as those by the US fleet; otherwise, a moratorium could be imposed on importing tuna from that country.

The 1992 International Dolphin Conservation Act required no import of any tuna caught in association with incidental dolphin mortality to the US after 1994 (Bean and Rowland, 1997). This and similar laws have been challenged by other nations for inhibiting the free trade agreed to under the General Agreement on Tariffs and Trade.

Endangered Species Act of 1973

The 1973 Endangered Species Act (ESA) is one of the strongest, and most controversial, federal biodiversity conservation laws. ESA has a broad mandate to restrict the taking of species that are at risk of becoming extinct, protect and acquire the habitat necessary for those species to survive, regulate their trade, and force all federal agencies to evaluate the impacts of their activities on endangered species and to avoid jeopardizing a species’ continued existence. This act was intended to enable the recovery of the populations of species it protects and the habitats that those species depend on. An endangered species is defined by the act as one that is in danger of extinction throughout all or a significant portion of its range. A threatened species is considered likely to become endangered in the foreseeable future throughout all or a significant portion of its range. The ESA is administered by the Interior Department’s US Fish and Wildlife Service (FWS) and the Commerce Department’s National Marine Fisheries Service (NMFS). The FWS is responsible for terrestrial and freshwater organisms and the NMFS is responsible for marine wildlife and anadromous fish such as salmon. The act outlines detailed procedures for the Secretary of Interior or Commerce to follow in listing or delisting a species as threatened or endangered (Houck, 1993). The decision must be based on objective scientific information on the biological status of the species and not on its economic or other value. Until a species is listed, it does not receive most of the protections of the act and the Department of Interior has a large backlog of species in the listing process.

The ESA outlines many duties and prohibitions that apply to all people subject to US laws (in Section 9) and other duties

that apply only to federal agencies (in Section 7). It is illegal to take any endangered or threatened animal species; take means to harm, harass, pursue, hunt, shoot, wound, kill, trap, or capture. Regulations further define harm to include habitat degradation to the point that wildlife is injured or killed. Although the original act did not prohibit taking of plants, later amendments prohibited taking plants on federal lands and prohibited removing or destroying plants on nonfederal lands where such action violated other laws.

Federal agencies are prohibited by Section 7 from approving, funding, or directly undertaking actions that are likely to jeopardize the continued existence of an endangered or threatened species or result in the destruction or adverse modification of its designated critical habitat. These agencies must consult with the Department of Interior or Commerce to determine the potential for jeopardy to the species or harm to its critical habitat and reasonable ways to avoid such harm. There is no direct legal obligation under ESA for nonfederal agencies or persons to avoid adverse modification of critical habitat.

In 1978, the Supreme Court ruled that the Tellico Dam in Tennessee could not be completed in order to prevent extinction of the endangered snail darter fish since the dam's reservoir would inundate the snail darter's habitat. Soon after this decision, Congress amended the ESA to allow the USFWS to take economic considerations into account when designating critical habitat and to allow a process for seeking exemption from the act's restriction on federal agencies. In 1982, Congress again amended the ESA to add section 10(A), allowing the Department of Interior to permit "incidental" private takings of endangered or threatened species if it was part of an approved Habitat Conservation Plan that would help reduce the risk to the species overall.

Section 7 also requires designation of critical habitat for species listed as endangered or threatened. Critical habitat is defined as an area critical to the survival of the species; this could include a portion of the area occupied by a listed species or an area beyond currently occupied habitat. Although the requirement to protect critical habitat has been applauded by many, it has been difficult to implement, and designations of critical habitat by the Department of Interior or Commerce have been rare. The requirement has resulted in a great deal of litigation brought both by those challenging critical habitat designations and by those challenging the agencies for their failure to make them.

The ESA can be enforced by the government through civil and criminal penalties and by citizens through citizen suits provided for in the act. Those who knowingly violate the ESA for an endangered species can be fined up to \$50,000 and put in prison for up to 1 year. For a threatened species, a violation can result in a \$25,000 fine and imprisonment for 6 months. Additional civil penalties can be imposed. States can participate in enforcement of ESA by signing cooperative agreements with the secretary of interior and are also eligible for federal financial assistance for enforcement.

An international mandate is also included in the ESA. The act directs the secretary of interior to encourage other countries to protect endangered species and authorizes financial support and assistance from US wildlife officers for such programs. Implementation of CITES is also authorized by ESA.

As of March 2011, the FWS had listed 1967 species worldwide as endangered or threatened; 1372 of those species occur in the US. The goal of the ESA is to help a species recover a large enough population to ensure that it is no longer at risk of extinction and can be taken off the threatened and endangered list. As of 2005, 40 species had been delisted but just 17 of those had recovered; the remainder were delisted for reasons including taxonomic changes and extinction (Nagle and Ruhl, 2006).

The ESA is one of the most controversial federal environmental laws passed during the past century. Its' very specific, substantive, and legally binding provisions make it a target for continuous challenge from a variety of perspectives. Challenges have come from those who argue about whether ESA really helps protect species, inhibits use of private land, or applies to specific federal and private actions. The act forces attention to solving the problem of threatened and endangered species, with its wider attention to habitat conservation. This focus on solutions has increased discussion of how humans develop and use broad landscapes for economic production in areas with important biodiversity. More procedurally oriented laws are able to avoid controversy by not requiring the threats to biodiversity to be addressed. At the same time, those who believe that the irreversible nature of biodiversity loss warrants strong use of the precautionary principle argue that the ESA is too weakly precautionary because it requires so much scientific evidence to support listing and when species are finally listed as threatened or endangered it is often too late for populations to recover (Saterson, 2011).

Fishery Conservation and Management Act (Magnuson Act) of 1976

Beginning in the early 1900s, international agreements between nations fishing in the same waters attempted to establish control of exploitation of ocean fish; by the 1970s the US was a party to approximately 20 such agreements (Bean and Rowland, 1997). Although waiting for agreement on a single international convention on fishing, the US passed the Fishery Conservation and Management Act in 1976. The act established a 3-mile-wide territorial sea off the coast of the US and a 200-mile-wide exclusive economic zone (EEZ). Within the EEZ, the US claimed exclusive management authority over fish and all other forms of marine animal and plant life except birds, mammals, and tuna. Tuna was added to this authority in 1990 amendments. The US also claimed authority to manage certain sedentary species found in places where the continental shelf extends beyond 200 miles from shore.

The act required eight Regional Fishery Management Councils, which include state and federal officials, to develop comprehensive plans for conserving and managing the fisheries off their coasts. These plans have to comply with standards that include preventing over-fishing and ensuring a maximum sustainable yield. The 1996 reauthorization of the act created new standards for minimizing "bycatch" (the accidental harvest of fish species not intended for harvest) and required that management plans try to minimize adverse impacts on fish habitats. Implementation authority for the act lies with the National Marine Fisheries Service in the Commerce Department. An important and controversial issue is

the extent to which international trade agreements, such as the General Agreement on Tariffs and Trade or the North American Free Trade Agreement, have the potential to conflict with, and undermine, national laws aimed at protecting biodiversity.

Conservation of Habitats and Ecosystems

During the past 40 years, legislators, administrators, and the general public have come to understand that species are not effectively conserved without protecting their habitats and ecosystems. The ESA reflected this by requiring conservation of critical habitat. Implementation of ESA has increasingly focused on habitat conservation plans as a way to conserve species. Many federal agencies have developed ecosystem management approaches to conserving lands and ecosystems in their entirety in order to complement species-oriented laws. Although an ecosystem management act was introduced in Congress and some have proposed an Endangered Ecosystem Act, a single regulatory approach to conserving US ecosystems is not legislated. The European Union's 1979 Wild Bird's Directive, supplemented by the 1992 Habitat Directive requires EU member states to protect specific habitats and all bird species before there is evidence of population decline, creating one of the first applications of the precautionary principle to protected areas (Saterson, 2011).

One important and threatened habitat type, wetlands, receives protection through the US Clean Water Act of 1972. The dredge and fill permit program in Section 404 of the act is a significant force in protecting aquatic ecosystems by regulating the physical alteration of "waters of the US," including wetlands, estuaries, and streams. In 2001, the US Supreme court ruled that this authority extends to wetlands that are adjacent to or have an effect on navigable waters of the US, but does not extend to isolated wetlands.

Federal Lands

Legislation and regulations addressing conservation of habitats and ecosystems in most countries focus primarily on creation of protected areas on publicly owned lands. On average, less than 5% of a country becomes legally designated as protected, and enforcement of that limited area of protection is often weak. Many protected areas allow some consumptive use of plant and animal species. An increasing number of countries have legislation that requires special permits to clear native vegetation or special habitat types outside of protected areas.

In the US, approximately 30% of the land area (more than 700 million acres) is owned by the federal government and managed primarily by four agencies. Congress has enacted separate laws outlining how each agency should manage its lands. Historically, public land management agencies have given high priority to production of a commodity, such as timber, grazing land, or waterfowl production, and put less emphasis on maintaining the health of an ecosystem and its biodiversity. The 1964 Wilderness Act authorized Congress to designate portions of any federal land as wilderness areas, in which new commercial enterprises and permanent roads are prohibited and natural ecological processes are supposed to be

allowed to occur without interference. During the early 1990s, federal agencies were directed to begin using "ecosystem management" to administer their lands. A level of production of a particular biological resource is to be considered in light of the health of the entire ecosystem.

Only the National Wildlife Refuge System (created in 1966) and the National Marine Sanctuary System (created in 1972) have as their primary goals the conservation of wildlife and marine resources, respectively. The National Marine Sanctuary Act of 1972 authorizes the secretary of commerce to designate sanctuary areas to "maintain, restore, and enhance living resources" by providing critical habitat for endangered species and areas where ecosystem structure and function are maintained. The National Wildlife Refuge System Improvement Act of 1997 consolidated refuge-related authorities and stated the mission of the National Wildlife Refuge System. The system's mission is to administer a national network of land and water "for the conservation, management, and restoration of fish, wildlife, and plant resources and their habitats" and to maintain the system's biological integrity and diversity.

National Park Service Act (1916)

The National Park Service Act outlines the goals and administrative guidelines for conserving the scenery, natural and historic objects, and wildlife in the national park system (which includes parks, monuments, preserves, wild rivers, and lakeshores) in a manner that does not impair those resources for future generations. There have been many instances in which the National Park Service has had to balance the (occasionally) conflicting goals of wildlife management and human recreation. Amendments to the act in 1978 provided the secretary of interior with some authority to protect park resources from outside threats, such as logging on private lands adjacent to parks. Courts have also upheld National Park Service authority to prohibit or regulate fishing, trapping, and hunting within park lands.

National Forest Management Act of 1976

National forest lands in the US began to be set aside in the late 1800s, with the primary purpose of protecting water supplies and timber production. The 1960 Multiple-Use Sustained-Yield Act (MUSY) expanded the purpose of national forests to also include outdoor recreation, grazing, timber, watersheds, fish, and wildlife. Concerned that the US Forest Service was giving timber production more attention than other multiple uses, Congress passed the 1976 National Forest Management Act (NFMA) which required the creation of management plans for each national forest. The plans are required to integrate physical, biological, and economic issues in order to provide for a diversity of plant and animal communities, including viable populations of native vertebrates. The plans are supposed to outline how timber harvests will mitigate impacts on biological diversity.

One of the most famous ecosystem management plans resulting from this legislation was for the old-growth forest in the Pacific Northwest. The Forest Service, after several court cases, was forced to develop a plan for old-growth forest that managed for a diversity of plant and animal species, including the spotted owl. Once the spotted owl was listed under the

ESA, the management plan had to comply with both ESA and NMFA.

Private Land

Individuals and institutions privately own approximately 60% of the US land area. Many of the previously discussed laws, such as the ESA and Section 404 of the Clean Water Act, aim to regulate actions with adverse impacts on biodiversity on private lands. Other federal laws aim to create positive financial incentives for conservation on private lands.

The 1985 Food Security Act included creation of a Conservation Reserve Program with the goal of encouraging farmers to voluntarily remove marginal lands from intensive agricultural production and plant them in perennial grass or tree cover for at least 10 years. A farmer enters into a contract to keep land in the reserve program for 10–15 years in exchange for cash or commodities. In addition, the farmer might receive up to 50% of the cost of certain conservation practices, such as creating wildlife corridors.

Biodiversity on private lands can also be conserved through donation or purchase of conservation easements. An easement is an interest in land that restricts the owner's use of the property in some way. The easement holder, usually a private interest or a government, has the right to enforce the restriction in perpetuity or for an agreed on time period. Since the 1970s, the Fish and Wildlife Service has been negotiating easements on wetlands as waterfowl production areas. The 1990 Food, Agriculture, Conservation, and Trade Act created a Wetlands Reserve Program through which the government purchases easements on wetlands from farmers, who then restore and protect the functional values of the wetland. The farmer is eligible to receive a share of the costs of implementing the land management plan for the easement. A similar Environmental Easement Program was created at the same time. Under this program, the government purchases easements on areas critical for wildlife on farms and ranches. The Forest Legacy Program, created in 1990, allows the secretary of agriculture to purchase conservation easements on forest areas that are threatened with development for other uses.

The 1969 US Internal Revenue Code began permitting landowners to take a charitable tax deduction for qualified conservation easements, thus creating an incentive for private landowners to protect their lands. Protection of natural habitat for plants and animals is one conservation purpose that qualifies an easement for tax deduction. This legislation has led to a dramatic increase in donation of conservation easements on private land to nonprofit land conservation organizations.

The 1985 and 1990 Farm Bills contained a strong incentive, in the "swampbuster" provisions (Highly Erodible Land Conservation and Wetland Conservation Compliance provisions), for farmers to maintain wetlands and not convert them to agricultural production. Anyone who drained, dredged, filled, or altered a wetland in order to produce an agricultural product would lose their eligibility for federal price supports, crop insurance, the Conservation Reserve Program, and all other federal benefits for all of their land and agricultural products. Other provisions of the Farm Bill also encourage protection of wetlands.

Other National Laws

National Environmental Policy Act of 1969

The most significant provision of the National Environmental Policy Act (NEPA) for biodiversity is the requirement that federal agencies prepare an Environmental Impact Statement (EIS) for every federal action or major legislative proposal that can have a significant impact on the environment. The EIS is expected to address potential impacts of proposed programmatic or site-specific actions on the environment, including biodiversity. An important feature of NEPA is the requirement that there be a public comment period on the draft EIS, and that public concerns be addressed in the final EIS. Most federal agencies evaluate the effects of their programs and projects on threatened and endangered species and sensitive habitats. However, many EISs have given inadequate attention to impacts on less threatened species, to overall habitat impacts, and to cumulative impacts on biodiversity.

Foreign Assistance Act of 1962

The 1962 Foreign Assistance Act (FAA) authorized the creation of the US Agency for International Development (USAID) and had little to say about environmental issues. Many of the areas of highest species diversity are located in developing tropical nations with insufficient economic resources to adequately protect biodiversity. As scientists and US citizens became aware of the global loss of biodiversity in the late 1970s, they began to lobby the US Congress to amend the FAA to ensure that US foreign aid to other countries helped to conserve biological diversity and tropical forests. Beginning in 1982, amendments to the FAA have required that the US assist developing nations with protection of habitats in protected areas, antipoaching measures for species, and research on biodiversity. Many of the most important and threatened national parks in developing countries now receive a significant portion of their operating budgets from bilateral assistance provided by developed nations. Sections 118 and 119 of the FAA require that USAID produce an annual report on the status of tropical forests and biodiversity in nations receiving US bilateral assistance.

Beginning in 1979, Section 216 of the FAA required that all US-funded development projects conduct environmental impact assessments to ensure that tropical rain forests and other biologically important habitats were not adversely impacted. USAID is also required to monitor the impacts of other multilateral donor projects, particularly those funded by the World Bank, and to provide input to the US representative to the World Bank about projects of environmental concern.

State and Local Legislation

The relative brevity of the following description of state and local laws should not imply that state and local legislation and regulations have less potential to contribute to conservation of biodiversity. In fact, the opposite is true. The following brief sections merely skim the surface of the laws for 50 states and thousands of municipalities in the US.

State Laws

All of the international and national laws and regulations outlined previously in this article have their impacts at local levels. Primary responsibility for stewardship of biological resources is reserved to states by the 10th Amendment to the US Constitution, which states that all powers not given to the federal government by the Constitution are retained by the states. Federal laws usually define minimum standards for the states to follow. States can, and sometimes do, pass laws that are more restrictive than federal laws in protecting plant and animal species, wetlands, forests, and other ecosystems.

States are responsible for managing the wildlife resources within their borders. Historically, most states have focused their wildlife conservation activities on a relatively small number of hunted or fished species. States retain authority to regulate and legislate many issues related directly to conservation of biodiversity; for example, managing the natural and biological resources on state-owned lands, setting hunting limits on deer and other resident, nonmigratory species, and approving permits for development and other projects that affect many habitats and species on privately owned land. State environmental law related to air and water quality and waste management can help to protect biodiversity indirectly. Perhaps the largest impact of state laws and local ordinances on biodiversity relates to how well the laws regulate the approval of land development plans so as to protect natural habitats and mitigate the impacts of development on habitat fragmentation and degradation.

State planning laws related to growth management and to land use planning can contribute to conservation. Thirteen US states have adopted growth management laws that require state plans to consider conservation of natural resources, wildlife, forests, and critical natural areas ([Environmental Law Institute and Defenders of Wildlife, 2003](#)). Many states also require that municipalities develop comprehensive plans, which might address conservation of biological resources along with land use and development issues. A number of state land use planning laws include mandatory elements such as natural resources, open space, wildlife habitat, and critical and sensitive areas ([Environmental Law Institute and Defenders of Wildlife, 2003](#)).

Only a small number of states have passed laws and regulations specifically addressing conservation of genes, species, and ecosystems, although the number is increasing. In 1992, the state of Michigan passed a Biological Diversity Conservation Act that required creation of a state biodiversity conservation strategy. A 1993 statute in New York State established a Biodiversity Research Institute with a mandate to coordinate state and private efforts to collect information about the state's biodiversity. The law also directed the New York Department of Environmental Conservation to implement programs to conserve rare and endangered species on state lands. In 1996, the state of Wisconsin passed a bill that revised the state's forest statute to ensure that management of state forests is consistent with maintaining native biodiversity and sustainable ecosystems. Many states have statutes that authorize creation of conservation easements on private lands. Hawaii created a statutory tax incentive that provides owners of forest or water reserve lands with relief from all property

taxes in exchange for allowing the state to manage their lands. Hawaii also has strong statutes to control the introduction of exotic species.

Many states, including California and Tennessee, have created executive orders and memoranda of understanding regarding conserving biodiversity, but these do not have the force of law. Many other states have policies aimed at conserving biodiversity by creating land acquisition programs for areas with important biodiversity, prohibiting introduction of exotic plant and animal species, and requiring environmental impact assessments in order to minimize and mitigate the impacts of development projects on biodiversity.

Many states are involved in legislatively mandated, regional initiatives to conserve ecosystems that cross state boundaries. The 1987 Chesapeake Bay Agreement was signed by Virginia, Pennsylvania, Delaware, Maryland, the District of Columbia, the Chesapeake Bay Commission, and the US Environmental Protection Agency. The signatories agreed to work on a program to conserve the biological resources and water quality of the Chesapeake Bay system.

Local Ordinances

Local laws can be enacted by municipalities, towns, cities, counties, townships, or boroughs, depending on their regulatory authority and on what local government units are called in different parts of the US. Although ultimately all biodiversity is conserved or lost at a local level, rarely are local laws primarily concerned with biodiversity per se; rather, they tend to focus on biological resources that indirectly influence public health, safety, or welfare (e.g., protecting wetlands or wooded slopes to control floods or regulating hunting for safety or to maintain economic benefits). Increasingly, however, concerned citizens have been working to ensure that local laws do consider conservation at some scale. Local governments can address biodiversity through broad municipal comprehensive planning and through municipal ordinances that address specific human activities that affect biodiversity on a more site-specific level.

Whether required by state law or not, many municipalities create comprehensive plans that address future land uses in the context of economic growth and quality of life, including conservation of biological resources. Many comprehensive plans include sections on natural or environmental resources. Some municipalities are beginning to prepare separate plans for "open space" – undeveloped land that often contains natural habitats. Most open space plans identify specific environmentally important habitats and recommend specific conservation strategies for those habitats.

Municipalities have adopted a variety of ordinances intended to minimize impacts on species and natural habitats; often, these ordinances support the resource conservation goals established through comprehensive or open space plans. An increasing number of municipalities are enacting ordinances that offer stronger protection to stream and wetland ecosystems than the requirements of state and federal law. Some municipal ordinances focus on integrating protection and restoration of habitats with land development project approvals. For example, some local ordinances have required that development projects maintain or create natural vegetated

buffers of more than 25 ft along wetland boundaries and more than 75 ft along each side of a stream.

An increasing number of municipalities have passed forest conservation ordinances that limit development in woodlands and penalize developers who harm those habitats. Some municipalities will not approve logging permits for sensitive woodlands without implementation of a forest management plan that demonstrates sustainable practices such as leaving buffers along streams, restricting logging to seasons when birds are not nesting, or leaving dead trees standing for wildlife habitat. Forest conservation ordinances have required developers to demonstrate that their plans will minimize unnecessary forest fragmentation and will not exceed the percentage of any woodland allowed to be cut. Plans that exceed the legal cutting percentage might only be approved if the developer mitigates the impact through reforestation or off-site forest conservation. Some ordinances seek to minimize tree removal by setting a limit on clearing around buildings and roads (e.g. 25 ft).

Many local municipalities in agricultural areas have ordinances that prohibit growing of introduced “weeds” that might decrease the productivity of agricultural crops. In some residential municipalities, weed laws have been replaced with natural landscaping ordinances that promote and govern natural alternatives to lawn grasses, such as wildflower meadows and reforestation.

Conclusions

The evolution of government legislation and regulation of biodiversity during the past 100 years reflects both the dramatic increases in human impacts on biodiversity in every part of the earth and the increased understanding of the structure and function of the natural world and how it responds to human activity. Legislation has evolved from individual nations focusing on single species of economic value to multi-national agreements aimed at protecting entire habitats and ecosystems. The five greatest current threats to biodiversity are habitat alteration and destruction; over-exploitation of species; invasive alien species; climate change; and nutrient loading and pollution. The laws summarized in this article address these threats to varying degrees. Despite improvements in legislation and regulations aimed at conserving biodiversity, the earth continues to lose genes, species, habitats, and ecosystems at a rapidly increasing rate.

There are many challenges to the effectiveness of the laws and regulations described in this article. Perhaps the greatest challenge is ensuring that existing laws are implemented as intended and then enforced. Many laws require scientific information on the status of species and ecosystems; such information is often unavailable or extremely costly to obtain. Many federal, state, and local government agencies charged with implementing conservation laws are challenged by insufficient resources to do so. Federal, state, and local implementing agencies are often pressurized by special-interest groups to compromise conservation mandates in favor of short-term economic gains. The laws in many countries go unenforced due to lack of oversight from private citizens and

advocacy groups. Finally, most laws are based on prohibiting actions that harm biodiversity; such laws can be supplemented by additional legislation that creates positive incentives for conserving and enhancing biodiversity. Legislation that creates increased positive incentives could be particularly beneficial for biodiversity on private land since private landowners control 60% of the land in the US.

Although the laws and regulations regarding conservation of biodiversity have generally improved significantly during the past 30 years, it is important to acknowledge that they can be amended and weakened whenever the various levels of government, from international to local, choose to do so. Equally important, many laws and regulations in other sectors create incentives to destroy biodiversity, such as logging subsidies, underpriced grazing rights, subsidies for economic development, and international trade policies. An additional challenge in regulating species, habitat, and ecosystem conservation is the difficulty in separating natural rates of change in populations and ecosystems from changes that result from human activities that can be regulated. The goal is to conserve the natural process of change and evolution and to determine the “signals” for when human activity is leading to adverse impacts on species and ecosystems so that those impacts can be prevented before they occur.

Biologists and Biodiversity Before 1986

Since ancient times, scholars have simultaneously revered the natural world, attempted to discover a natural order in that world or impose rational order on that world, and sought to understand the place of humans in the cosmos based on what they read in the natural world.

Worster (1987), Bowler (1993), and other historians offer extensive treatments of pre-twentieth century attempts by biologists and their intellectual predecessors to understand, categorize, and philosophize the natural world. In the mid-eighteenth century, for example, in order to fathom God's wisdom, Carolus Linnaeus classified the riot of life into a functional taxonomy, the *Systema Naturae*. In "The Oeconomy of Nature" (1749), Linnaeus offered a protoecological treatise on how these life forms fit together in mutual, stable interdependence, with humans at a central nexus in the web. For Linnaeus and his contemporaries, God meant humans to use those species that we found valuable; the complexity and richness of the natural world meant that our use of nature could not upset what God had balanced so exquisitely.

A century later, Charles Darwin built on Linnaeus's and others' ecological and taxonomic groundwork and painstakingly laid out a theory that provided an historical, deterministic explanation for the relatedness of all God's creatures – even if his work made God seem a bit less relevant and humans a bit less central to the machinery of nature. Darwin saw all forms of life as human kin and believed a key to civilization's maturity was the ability to empathize with and respect our extended family. For both Linnaeus and Darwin, the diversity of earth's life forms was a phenomenon to be revered, contemplated, and explained. Neither of them envisioned the object of their study as a commodity that needed protection from human advances, although a contemporary of Darwin's, Marsh (1864/1965), did begin to grasp this in his prescient *Man and Nature*. Marsh warned that human activity was destroying natural functions, and that this destruction threatened to undercut the survival of our own species.

In the twentieth century, some biologists looking for meaning in the diversity of life added to the trio of reverence, imposition of order, and search for deeper meaning about humanity. Biologists came to understand and document that the grand panoply of life forms was threatened as the fabric of ecological connections was rent. This awareness led biologists to make leaders and laypersons aware, and they searched for ways to use their carefully tended scientific authority to make nonscientists care about and conserve the objects of their reverence. Such work carries perils: advocacy threatens to undermine the perception of value neutrality and objectivity that leads laypersons to listen to scientists in the first place.

In *A Sand County Almanac II*, wildlife ecologist Leopold (1949/1970) proposed a "land ethic" that we should follow if we are to revere nature's diverse organisms and protect them

to play the precise roles in nature's scheme that ecological scientists were just beginning to elucidate:

If the biota, in the course of aeons, has built something we like but do not understand, then who but a fool would discard seemingly useless parts? To keep every cog and wheel is the first precaution of intelligent tinkering (p. 190).

Leopold asserted that all species are intertwined in complex interrelationships, and the diversity of organisms and their interrelationships are crucial for a stable, functioning planet. From the "is" of ecology, Leopold derived the "ought" that forms the basis of his land ethic:

A thing is right when it tends to preserve the integrity, stability, and beauty of the biotic community. It is wrong when it tends otherwise (p. 262).

British ecologist Elton (1958) also viewed "ecological variety" as a threatened commodity. In *The Ecology of Invasions by Animals and Plants*, he foretold the dangers that humans would face as anthropogenic introductions of nonendemic species sweep the globe and threaten the flora and fauna that had previously been left to evolve in splendid isolation:

It is not just nuclear bombs and wars that threaten us, though these rank very high on the list at the moment: there are other sorts of explosions, and this book is about ecological explosions (p. 15).

Like Elton, Carson (1962/1987) warned that people could no longer take this variety for granted as benign backdrop to human affairs. Rather, ecological science taught that species diversity is essential for ecological and human health and that uncontrolled pesticide-use threatened this diversity. Biologists like Leopold, Elton, and Carson still revered "natural variety," still sought to reveal the secrets of nature's order. But unlike pre-twentieth century natural philosophers, they desired that their readers come to view species diversity as a quantifiable, measurable entity that was inextricably bound up with their own well-being. Species diversity was now a threatened commodity, and humans who caused this threat were simultaneously threatened as this commodity diminished.

Creation of the Term "Biodiversity"

Throughout the 1960s and 1970s, biologists fomented public alarm over the deteriorating environment. Prominent biologists (e.g., Ehrenfeld, 1981; Ehrlich and Ehrlich, 1981; Myers, 1979) helped raise awareness that diversity was a threatened commodity, and US legislatures responded with laws designed to assuage the threat. Most notably, the 1973 Endangered Species Act (ESA) recognized and sought to protect the

paramount value of species diversity (Kohm, 1991). Recognizing that

species of fish, wildlife, and plants have been so depleted in numbers that they are in danger of or threatened with extinction

and that these forms of life

are of esthetic, ecological, educational, historical, recreational, and scientific value to the Nation and its people

the ESA commits the nation to preserving these species for current and future generations. While limiting its focus to species, and whittled down from its original ambitions by insufficient budgeting, cautious administrative bureaucrats, and restrictive judicial interpretations, the ESA remains one of the most powerful allies biodiversity has ever had.

Still, biologists were frustrated that efforts to protect diversity were not keeping pace with the furious rate of destruction. Walter G. Rosen, a biologist and senior program officer at the National Research Council (which advises the National Academy of Sciences (NAS)), brought together prominent scientists from the NAS with the clout of the Smithsonian Institution to host the National Forum on Biodiversity in 1986. At the National Forum, biologists and others concerned about imperiled diversity staged a consciousness-raising event that sought, and received, widespread attention from the public. Rosen coined the neologism “biodiversity” for the event as a convenient shorthand, a buzzword that would at once encapsulate biologists’ understanding of a chaotic, diminishing natural world, and would raise public awareness about threats to the natural world (Takacs, 1996). In *BioDiversity* (Wilson, 1988), the collection of essays that chronicled the National Forum, Paul Ehrlich, Daniel Janzen, Tom Cade, Lester Brown, Michael Soulé, and other scientists declared the need to rouse public attention on behalf of biodiversity and exhorted their colleagues to adopt that mission.

As biologists promote the term and the complex worldview it represents, “biodiversity” has become a widespread conservation buzzword. Biologists write about it in scientific and popular presses, both exploring its complexity and advocating its protection. Environmental groups focus on it in fundraising efforts; conferences convened in its name occur regularly. Laypersons have joined biologists in attempting to shape the planet’s physical, political, and normative environments to make more room for biodiversity.

Problems with Other Foci of Conservation Efforts

Why has “biodiversity” gained prominence as a conservation buzzword, and why have biologists speaking on its behalf had some success in shaping public opinion about threats to the natural world?

Various scholars (Cronon, 1995; Evernden, 1992; Williams, 1980) note that nature is so all-encompassing that what one attributes to it may say more about the speaker than it does about the natural world. Previous attempts to preserve “nature” or “wilderness” are too vaguely defined or deemed elitist in some quarters. For example, Guha (1989) sees traditional

advocacy for nature or wilderness preservation as setting the aesthetic desires of the rich against the needs of the poor who need land to survive. Guha’s critique has, to some extent, been incorporated into the biodiversity preservation discourse. For example, as people came to appreciate the value of cultural diversity, they might also see diversity in all its forms as a normative good, particularly when efforts to preserve both may be mutually reinforcing (Nabhan, 1997). A document prepared for the 1992 United Nations Conference on Environment and Development notes that

cultural diversity is closely linked to biodiversity. Humanity’s collective knowledge of biodiversity and its use and management rests in cultural diversity; conversely, conserving biodiversity often helps strengthen cultural integrity and values (Reid *et al.*, 1992, p. 23).

Prior to the advent of biodiversity, the most effective conservation efforts in the US focused on endangered species. Biologists’ foci changed because biodiversity represents a more sophisticated ecological worldview, and a more sophisticated view of what biologists want preserved and how they want it preserved. Biologists promoting biodiversity conservation also seek to circumvent certain problems arising from efforts to preserve endangered species.

Even though human activities accelerate the rate of species extinction, some opponents of conservation argue that species extinction is a natural process that we should let proceed. Biologists have difficulties defining with precision what constitutes a species (or a subspecies, like the Northern Spotted Owl) in the first place. We are not aware of the economic or ecological benefits some individual species confer, so it is difficult to argue for their conservation in some circles. Many of the insects, bacteria, plants, and other members of what Wilson (1987) calls “the little things that run the world” remain unidentified and unloved; invertebrates comprise only a tiny percentage of organisms protected by the US ESA. Land set aside to protect individual endangered species may prove insufficient if global warming induces species migration (Peters and Lovejoy, 1992). When we focus on species diversity, we sometimes ignore genic, population, community, or ecosystem diversity. Endangered species conservation proves to be nearly impossible in poorly explored areas, in oceans, and in nations without species checklists. Focus on species that are endangered can be a last minute emergency effort to save species that may no longer be playing functional ecological roles, and this strategy may be inferior to proactive efforts to preserve healthy populations in healthy ecosystems. Finally, some view the US ESA as a mixed blessing: its unyielding allegiance to species on the verge of extinction is also a political lightning rod that leaves little room for compromise and has set many citizens against conservation efforts (Mann and Plummer, 1995).

What is “Biodiversity”?

Elsewhere in this encyclopedia, one may read about definitions of biodiversity. In the research conducted by the author (Takacs, 1996), prominent biologists were asked to define the term “biodiversity.” Little, if anything, in the natural world is

excluded from these definitions of biodiversity. Responses included that biodiversity is “the complete array of organisms, biologically mediated processes, and organically derived structures out there on the globe” (Jerry Franklin); “the whole package of genes, populations, species, and the cluster of interactions that they manifest” (Daniel Janzen); “the total number of genetic lineages on earth” (Thomas Eisner); “shorthand for all the richness of life” (Reed Noss); or “the sum total of plants, animals, fungi, and microorganisms in the world including their genetic diversity and the way in which they fit together into communities and ecosystems” (Peter Raven). According to Terry Erwin (1991, p. 3), it is

the sum of earth species including all their interactions and variations within their biotic and abiotic environment in both space and time.

So biodiversity represents a rich, complicated vision of life and a corresponding rich, complicated vision of what biologists want to see preserved. Although few biologists wish to see any species slip into extinction, what they really want – and what biodiversity really represents – is preservation of ecosystems, of vast stretches of land where the evolutionary process may continue relatively unfettered.

But ecosystems are hard to delineate, and even mentioning “evolution” lights a powder keg in some quarters. Kellert (1986, 1996) notes that the public is most likely to rally around “cognitively meaningful” organisms. Habitat has no fur, and ecosystems lack big, expressive eyes that rouse public affection and therefore attention to conservation causes. With biodiversity, biologists can focus attention on the charismatic megavertebrates the layperson finds endearing. These organisms are emotionally and ecologically appealing to the conservation minded: they often are at trophic levels that require large territories to survive. When we preserve the large areas of land they require, we also fortuitously protect a myriad of species and enable continued functioning of ecological and evolutionary processes that biologists value.

Conservation efforts on behalf of biodiversity enable multiple images and multiple strategies to protect and conserve the natural world; many of those strategies place more power in the hands of biologists to realize their conservation values. If definitions of biodiversity seem complex and all encompassing, that is part of why it has been successful as a conservation tool. At once it represents the complexity of biologists’ worldview, the whole span of what biologists wish to conserve, and in it each of us can see that part of nature we cherish.

Biologists and the Promotion of Biodiversity

When biologists speak about biodiversity, they simultaneously refer to small parts of the ecological world, the interrelatedness between those parts, the ecological processes that sustain those parts, and the evolutionary processes that gave rise to those parts. While appearing as a purely scientific, objective entity, biodiversity also encompasses political arguments on behalf of conservation and symbolizes much that biologists do not know about the natural world.

Biodiversity represents ecological complexity that, the more they study, the more biologists realize they do not understand. Biologists do not know, within an order of magnitude, how many species live on earth, so they cannot specify how many we are losing and cannot say what the loss of these species represents to the ecosystems or to the humanity’s future prospects (Stork, 1997; Tilman, 1999; quotes in Takacs, 1996). Biologists believe that if people are alarmed by such ignorance, they will simultaneously take precautions about dismantling an ecological world that supports us in myriad unknown ways, will support biologists’ research efforts to understand that world, and will listen to biologists’ policy prescriptions on how and why we ought to save that world. For example, the question that Wilson (1992) is most frequently asked about the diversity of life is:

if enough species are extinguished, will the ecosystem collapse, and will the extinction of most other species follow soon afterward? The only answer anyone can give is: possibly. By the time we find out, however, it might be too late. One planet, one experiment (p. 182).

In light of this uncertainty, Wilson urges

prudence. We should judge every scrap of biodiversity as priceless while we learn to use it and come to understand what it means to humanity (p. 351).

In Wilson’s view, biologists hold the key to that understanding.

Many who have come to call themselves conservation biologists cite this uncertainty as they attempt to have the public become aware of biodiversity and become concerned about its diminution. They warn that what we do not know about biodiversity will hurt us, and urge us that if we were to come to know it, our lives might have greater meaning. They seek a new ethic where biodiversity would be cherished. Leopold (1949/1970) sought this, and his “land ethic” laid the groundwork for a new way of valuing diversity. Leopold knew that

no important change in ethics was ever accomplished without an internal change in our intellectual emphasis, loyalties, affections, and convictions. The proof that conservation has not yet touched these foundations of conduct lies in the fact that philosophy and religion have not yet heard of it.

Today, a number of prominent biologists seek to have our intellectual emphases, loyalties, affections, and convictions match theirs. Some biologists see this as a crucial moment in history when they must help raise awareness of biodiversity; they see it as their responsibility to speak out about what they study and love so that subsequent human and natural history will reflect their values. For example, Janzen (1986) exhorts his fellow biologists:

Set aside your random research and devote your life to activities that will bring the world to understand that tropical nature is an integral part of human life.

Janzen is part of the “mission-oriented” discipline of conservation biology, which was founded not only to study biodiversity, but also to embrace its many values and to promote

findings that will help conserve the objects of study. Built into the discipline's foundations are normative principles or, as discipline founder Soulé (1985, p. 730) says,

value statements that make up the basis of appropriate attitudes toward other forms of life – an ecosophy.

The pages of the discipline's flagship journal, *Conservation Biology*, report not just the latest research findings; they are also filled with thoughtful articles on conservation education, policy implications of research, and spirited debates on what types of activism are required or appropriate for practitioners. Although some biologists feel they must advocate on behalf of the natural world they study and love, others fear that such advocacy threatens the scientific enterprise: If scientists are no longer perceived as objective and value neutral, why would societies fund their work and listen to their results?

Many scientists ignore the risks of advocacy and proselytize on behalf of biodiversity. Some well-known biologists (e.g., Wilson, Raven, Eisner, and Lovejoy) have spoken before Congress on the value of biodiversity. Others testify in courts as expert witnesses on behalf of biodiversity. Paul Ehrlich and others appear on radio and television to raise awareness about biodiversity. Many biologists write for the popular press or speak to general audiences on the values of biodiversity. They talk to garden clubs, and preach in church pulpits. Lovejoy takes senators, movie stars, and other influential people to the Brazilian Amazon so that they may experience biodiversity

in a way words can't touch. ... And it has never failed to be a truly touching experience for them (Takacs, 1996, p. 153).

By helping laypersons become aware of biodiversity's beauty and fragility – by tireless efforts to, in the words of the “Father of Biodiversity” Wilson, “educate, educate, educate” (quoted in Anonymous, 1994) – biologists hope for widespread transformation of values. That transformation of values might lead to what Ehrlich (1985) calls a “quasireligious transformation” of feelings toward the wonders of the natural world, which would presumably be translated into action to conserve those wonders.

Many prominent North American biologists work in far-flung corners of the earth to raise awareness of biodiversity, particularly in tropical nations that hold the greatest concentrations of diversity, and which face the greatest imminent threats to that bounty. In Costa Rica, a small country with perhaps 5% of the world's species diversity, biologists have spurred a national effort not only to preserve biodiversity in protected areas, but also to catalog biodiversity and to search for the economic wealth contained within. At Costa Rica's Instituto Nacional de Biodiversidad, specimens of plants, insects, and other taxa are sorted and sent to multinational pharmaceutical companies for research. Profits from successful drugs deriving from Costa Rica's biodiversity would be funneled back to the areas where the biodiversity flourishes. In effect, this is an experiment in which biodiversity would pay its own way, with biologists driving the process.

Specimens are collected by a large group of rural-dwelling parataxonomists. As they tromp around the nation's forests, the idea goes, they will lead a movement in “biocultural

restoration”: by becoming reenchanting with biodiversity, they will be compelled to spread their new knowledge and appreciation to their neighbors. Through renewed awareness – and renewed economic dividends – rural dwellers would be empowered and inclined to protect their biodiversity patrimony (Evans, 1999; Gámez *et al.*, 1993; Janzen, 1988).

The Values of Biodiversity

In Costa Rica, and in many other corners of the earth, biologists are working to raise awareness of the many values of biodiversity. Biologists hope that biodiversity's appeal to many different audiences will spark diverse efforts to preserve it. Some of the values that biologists attribute to biodiversity find their loci in biodiversity itself; in most, though, humans are the value holders.

As we might expect, biologists promote the value biodiversity holds for science, as the raw material for scientists' investigations: it is “Earth's living library” (Lovejoy, 1992). Also unsurprisingly, biologists speak extensively about biodiversity's ecological value. Biodiversity provides numerous “ecosystem services” (or, depending on your definition, “ecosystem services” is part of what constitutes “biodiversity”). That is to say, biodiversity keeps global ecosystems functioning. Biodiversity purifies water, controls agricultural pests, decomposes waste, pollinates plants, stabilizes global climate, creates soil, transports nutrients, controls erosion, and maintains the ecological matrix human society requires to exist at all (Daily, 1997; Tilman, 1999). And as humans attempt to repair damaged ecosystems, we will need reservoirs of intact biodiversity to restore what we have destroyed (Jordan, 1997).

For those who measure value in terms of money, biologists assert that biodiversity has vast economic value. Biologists note that biodiversity's value to functioning ecosystems is priceless – although Costanza *et al.*, (1997) have tried to calculate the incalculable. Costanza's team figured that 17 ecosystem services in 16 biomes contribute between 16 and 54 trillion (US) dollars per year to human economies, and they believe this is a conservative estimate. This, they note, is higher than the global gross national product of 18 trillion dollars per year. Janzen (1986) offers an exhaustive list of the treasures that biodiversity already has directly provided human society. Others (e.g., Wilson, 1992) discuss the lucre that can be gained from the hidden food, medicine, chemicals, fibers, and other goods lurking in the world's natural places. As noted earlier, Costa Rica has invested heavily in its biodiversity; through ecotourism and bioprospecting, the nation is profiting from its biodiversity resources. Biologists (e.g., Janzen, 1990) also tout biodiversity's social amenity value: it can contribute to sustainable development efforts (through direct harvesting or ecotourism), foster national pride, or help those living nearby to lead more intellectually and aesthetically fulfilled lives.

Wilson (1992, 1998) has been the leading proponent of biodiversity's value to fulfill our biophilic impulses. Wilson and others believe that love of nature has been hardwired into our genes, and we can only be truly fulfilled by satisfying that love. Those whose biophilic passions have been rekindled will also be those who work hardest for biodiversity

preservation: others refer to this as biodiversity's "transformative value." Philosopher Norton (1987) explains how interactions with biodiversity can help us reconsider our consumerist impulses and make us convert to lifeways that preserve the biodiversity that provided the impetus for transformation. Biodiversity's aesthetic value – the beauty of an individual organism and its adaptations, of landscapes, of intricate ecological processes, of the sheer riot of different life forms – may effect this kind of transformation.

When biologists suggest that biodiversity may transform us, may reawaken our biophilic impulses, they still place the locus of its value in the human valuer. Some biologists take a different tack and assert that biodiversity has intrinsic value, independent of a human valuer. This concept is difficult to prove empirically and therefore difficult for a scientist to assert. Yet given the preceding definitions of "biodiversity," if biodiversity is the totality of life forms on earth, their interactions, and the processes that gave rise to them and to us, it makes it a more complicated proposition to reject the notion of biodiversity's intrinsic value out of hand. This notion takes a turn for the spiritual, and, in fact, some biologists also discuss biodiversity's spiritual value. Ehrenfeld (1981), who would become the founding editor of *Conservation Biology*, wrote of "The Noah Principle": species

should be conserved because they exist and because this existence is itself but the present expression of a continuing historical process of immense antiquity and majesty. Long-standing existence in Nature is deemed to carry with it the unimpeachable right to continued existence.

Some biologists (see quotes in Takacs, 1996) agree that the value inherent in biodiversity makes it sacred and others put the locus of value in humans, and they discuss the spiritual nourishment that contact with biodiversity brings.

The multiplicity of meanings of "biodiversity" is reflected in the multiplicity of values biologists find in it. For those biologists who would raise awareness of biodiversity's plight, it makes sense to speak for as many different values – and therefore to as many different audiences – as possible.

International Awareness Grows, Biodiversity Continues to Dwindle

Efforts to raise awareness about biodiversity continue unabated. One-hundred and sixty-eight nations have signed the Convention on Biological Diversity, whose objectives are

the conservation of biological diversity, the sustainable use of its components and the fair and equitable sharing of the benefits arising out of the utilization of genetic resources... (Convention on Biological Diversity, 2011a, b).

Despite nearly 20 years of meetings and plans and firm targets (see, e.g., the Strategic Plan for Biodiversity 2011–2020, Convention on Biological Diversity, 2011c), and with the heralding of 2011–2020 as the "United Nations Decade on Biodiversity," the web of life on Earth continues to unravel. The Secretariat of the Convention on Biological Diversity, despite noting some tepid bright spots (e.g., more nations

with biodiversity plans and a slower rate of tropical forest loss), nonetheless asserts that a quarter of plant species are threatened, amphibians and coral reefs lead other species groups on the march to extinction, and most habitats of the world are increasingly fragmented or degraded (Convention on Biological Diversity, 2010). Similarly, the European Union has a formal Biodiversity Strategy, with the heading, "Our life insurance, our natural capital" (European Commission, 2011). Recognizing that only 11% of key ecosystems and 17% of species and habitats protected by the EU are in a favorable condition, the Strategy nonetheless recognizes that their previous biodiversity target for 2010 would not be met, but pledges to do better this time around.

Inspired by an idea from Wilson, the "Encyclopedia of Life" seeks to establish "a webpage for every species" (more than 900,000 as of this writing) as a resource "to increase awareness and understanding of living nature" for "the general public, enthusiastic amateurs, educators, students and professional scientists from around the world" (EOL, 2011). The specter of global climate change has provided new urgency for efforts to raise awareness about the manifold threats to biodiversity, with new mechanisms like carbon offsetting for "Reducing Emissions from Deforestation and forest Degradation (REDD)" providing new financial means for preserving tropical biodiversity (Takacs 2010). Biologists are playing a key role in designing mechanisms and standards to ensure that funds invested in carbon offsetting conserve biodiversity; for example, the Climate, Community, and Biodiversity Alliance requires carbon offsets to result in "Net Positive Biodiversity Impacts" and requires biodiversity impact monitoring (CCB, 2011).

Historical Awareness of Biodiversity Redux

We can read the title of this encyclopedia entry in many ways. Smithsonian tropical biologist and biodiversity advocate Erwin says (in Takacs, 1996, pp. 100–101):
